## Chapter 1

### Introducción

Scala integra sin irregularidades la programación orientada a objetos y la programación funcional. Se diseñó para expresar patrones de programación comunes de una manera concisa, elegante y con tipado seguro. También introduce varias innovaciones en la construcción del lenguaje. Por ejemplo:

- Conceptos unificadores de tipos abstractos y composición de mezcla del los sistemas de objeto y módulo.
- Los patrones concordantes sobre jerarquía unifican cómo tener acceso a información funcional y orientada a objetos. Esto simplifica enormemente el procesar árboles XML.
- Una sintaxis flexible y un sistema de tipado que habilitan la construcción de bibliotecas avanzadas y nuevos lenguajes de dominio específico (DSL, por sus siglas en inglés, *Domain Specific Language*).

Al mismo tiempo, Scala es compatible con Java. Las bibliotecas de Java y los *Frameworks* escritos en el, se pueden utilizar sin código pegamento o declaraciones adicionales.

Este documento introduce Scala de una manera informal, mediante una secuencia de ejemplos.

Los capítulos 2 y 3 enfatizan algunas de las características que hacen a Scala interesante. Los siguientes capítulos introducen los constructos del lenguaje Scala de manera más cuidadosa, comenzando con expresiones y funciones simples, y trabajando sobre y mediante objetos y clases, listas y *streams*, estados mutables, concordancia de patrones, a ejemplos más complejos que muestran técnicas de programación interesantes. La presente exposición informal tiene la intención de complementarse con el Manual de Referencia del Lenguaje Scala, el cual especifica Scala en una manera más detallada y precisa.

2 Introducción

**Reconocimiento.** Estamos en gran deuda con el maravilloso libro "Structure and Interpretation of Computer Programs" [?] de Abelson y Sussman. Muchos de sus ejemplos y ejercicios también están presentes aquí. Por supuesto, al trabajar con el lenguaje se ha cambiado en cada caso de Scheme a Scala. Además, los ejemplos hacen uso de los constructos orientados a objetos donde es apropiado.

## Chapter 2

## Un primer ejemplo

Como primer ejemplo, aquí está una implementación de un Quicksort en Scala.

```
def sort(xs: Array[Int]) {
  def swap(i: Int, j: Int) {
    val t = xs(i); xs(i) = xs(j); xs(j) = t
 def sort1(l: Int, r: Int) {
    val pivot = xs((1 + r) / 2)
    var i = 1; var j = r
    while (i <= j) {
      while (xs(i) < pivot) i += 1
      while (xs(j) > pivot) j -= 1
      if (i <= j) {
        swap(i, j)
        i += 1
        j -= 1
      }
    }
    if (1 < j) sort1(1, j)
    if (j < r) sort1(i, r)
  sort1(0, xs.length - 1)
}
```

La implementación luce muy similar a como se escribiría en Java o C. Usamos los mismos operadores, y estructuras de control similares. Hay también otras diferencias sintácticas menores. En particular:

 Las definiciones comienzan con una palabra reservada. Con def comienzan las definiciones de las funciones, con var comienzan las definiciones de variables y con val comienzan las definiciones de valores (es decir, variables de 4 Un primer ejemplo

solo lectura).

El tipo de dato de un símbolo, se declara después del símbolo y dos puntos (:).
 La declaración del tipo de dato a menudo puede omitirse, ya que el compilador puede inferirlo del contexto.

- Los tipos de arreglo se escriben Array[T] en lugar de T[], y las selecciones del arreglo se escriben a(i) en lugar de a[i].
- Las funciones pueden anidarse dentro de otras funciones. Las funciones anidadas pueden tener acceso a parámetros y variables locales de las funciones donde están incluidas. Por ejemplo, el nombre del arreglo xs es visible tanto en la función swap, como en la función sort1, y por lo tanto no se les requiere pasar como un argumento.

Hasta ahora, Scala luce como un lenguaje convencional con algunas peculiaridades sintácticas. De hecho es posible escribir programas de una manera imperativa convencional o en estilo orientado a objetos. Esto es importante porque es una de las cosas que hace fácil combinar componentes de Scala con componentes escritos en otros lenguajes dominantes como Java, C# o Visual Basic.

Sin embargo, también es posible escribir programas en un estilo que luzca completamente diferente. He aquí un *Quicksort* de nuevo, pero esta vez escrito en estilo funcional.

```
def sort(xs: Array[Int]): Array[Int] = {
  if (xs.length <= 1) xs
  else {
    val pivot = xs(xs.length / 2)
    Array.concat(
        sort(xs filter (pivot >)),
              xs filter (pivot ==),
        sort(xs filter (pivot <)))
    }
}</pre>
```

El programa funcional captura la esencia del algoritmo *Quicksort* de una manera concisa:

- Si el arreglo está vacío o consiste de un solo elemento, entonces ya está ordenado, así que se regresa inmediatamente.
- Si el arreglo no está vacío ni es único, se selecciona un elemento a la mitad del arreglo como si fuera un pivote.
- Se parte el arreglo en dos subarreglos conteniendo elementos que, respectivamente, sean menores y mayores que el elemento pivote, y un tercer arreglo que contiene los elementos igual al pivote (con el método filter).

- Se ordenan los primeros dos subarreglos por invocación recursiva de la función de ordenación.<sup>1</sup>
- El resultado se obtiene al acomodar los tres subarreglos juntos.

Tanto la implementación imperativa como la funcional tienen la misma complejidad asintótica –  $O(N \log(N))$  en el caso promedio y  $O(N^2)$  en el peor caso. Pero donde la implementación imperativa opera sobre el arreglo que le llega como argumento modificandolo, la implementación funcional regresa un nuevo arreglo acomodado y deja el arreglo que le llega como argumento sin ningún cambio. La implementación funcional requiere más memoria transitiva que la imperativa.

La implementación funcional hace parecer a Scala como si fuera un lenguaje que se especializa en operaciones funcionales sobre arreglos. De hecho, no es así; todas las operaciones utilizadas en el ejemplo son simples métodos de biblioteca de una clase *sequence* Seq[T], los cuales son parte de la biblioteca estándar de Scala, ella misma implementada en Scala. Debido a que los arreglos son instancias de Seq todos los métodos de *sequence* están disponibles para ellos.

En particular, hay un método filter que toma como argumento una *función de predicado*. Esta función de predicado debe mapear los elementos del arreglo a valores *booleanos*. El resultado de filter es un arreglo consistente con todos los elementos de arreglo original para los cuales la función de predicado es verdadera (*true*en ingles). El método filter de un objeto de tipo Array[T] tiene esta estructura

```
def filter(p: T => Boolean): Array[T]
```

Aquí, T => Boolean es del tipo de funciones que toma un elemento de tipo T y regresa un Boolean. Las funciones como filter que toman otra función como argumento para regresar uno como resultado se llaman funciones *de orden mayor* (*higher-order functions* en inglés).

Scala no distingue entre identificadores y nombres de operador. Un identificador puede ser tanto una secuencia de letras y dígitos que comiencen con una letra, o pueden ser una secuencia de caracteres especiales, tales como "+", "\*", o ":". Cualquier identificador puede usarse como un operador infijo en Scala. La operación binaria E op E' se interpreta siempre como una llamada del método E. op(E'). Esto también aplica para operadores infijos binarios los cuales comiencen con una letra. Por lo tanto, la expresión xs filter (pivot >) es equivalente a la llamada del método xs.filter(pivot >).

En el programa Quicksort, a filter se aplica tres veces una función anónima como argumento. El primer argumento, pivot >, representa una función que toma a x como argumento y regresa el valor pivot > x. Este es un ejemplo de una función

<sup>&</sup>lt;sup>1</sup>Esto no es exactamente lo que hace el algoritmo imperativo; el llamado posterior de la función, parte el arreglo en dos subarreglos conteniendo elementos menores o mayores o iguales al pivote.

6 Un primer ejemplo

parcialmente aplicada (Partially applied function, en inglés). Otra manera equivalente de escribir esta función la cual muestra explícitamente al argumento faltante es x => pivot > x. La función es anónima, es decir, no se define con un nombre. El tipo de parámetro x se omite porque el compilador de Scala puede inferirlo automáticamente del contexto donde la función se usa. Para resumir, xs.filter(pivot >) regresa una lista consistente con todos los elementos de la lista xs que sean más pequeños que pivot.

Al mirar de nuevo en detalle a la primera implementación imperativa de *Quicksort*, encontramos que muchos de los constructos de lenguaje utilizados en la segunda solución están también presentes, no obstante, en una forma disfrazada.

Por ejemplo, los operadores binarios "estándar" tales como +, -, o < no se tratan de ninguna manera especial. Como append, son métodos de sus operando izquierdo. Consecuentemente, la expresión i + 1 se mira como la invocación i.+(1) del método + del valor entero x.

Por supuesto, un compilador es libre (y si es moderadamente inteligente, incluso se espera) de reconocer el caso especial en al llamar al método + sobre argumentos enteros y generar código eficiente para ello en una línea.

Para un diagnóstico de errores más eficiente y mejor, el ciclo **while** es un constructo primitivo en Scala. Pero en principio, bien podría haber sido una función predefinida. Aquí hay una posible implementación de él:

```
def While (p: => Boolean) (s: => Unit) {
  if (p) { s ; While(p)(s) }
}
```

La función While toma como su primer parámetro una función de prueba, lo cual no toma parámetros y produce un valor *boolean*. Como segundo parámetro toma una función de comando la cual tampoco toma parámetros y produce un resultado del tipo Unit. While invoca la función de comando mientras la función de prueba produce *true*.

El tipado Unit de Scala corresponde a grandes rasgos al void en Java; se usa siempre que una función no regrese un resultado interesante. De hecho, como Scala es un lenguaje orientado a expresiones, cada función regresa algún resultado. Si no se da una expresión de regreso explícita, se asume el valor (), que se pronuncia "unit". Este valor es del tipo Unit. Las funciones que regresan *Unit* también se llaman *procedimientos*. Aquí está una formulación más "orientada a expresiones" de la función swap en la primera implementación del *Quicksort*, que hace esto explicito:

```
def swap(i: Int, j: Int) {
  val t = xs(i); xs(i) = xs(j); xs(j) = t
  ()
}
```

El valor que retorna esta función es simplemente su última expresión – una palabra clave **return** no es necesaria. Nótese que las funciones que regresan un valor explícito necesitan un "=" antes de definir su cuerpo o de definir sus expresiones.

### Chapter 3

## Programando con Actores y Mensajes

Aquí tenemos un ejemplo que muestra un área de aplicación para la cual Scala es particularmente bueno. Considere la tarea de implementar un servicio electrónico de subastas. Usamos un modelo de procesamiento de actores (en inglés, *actor process model*) al estilo Erlang para implementar a los participantes de la subasta. Los "actores" son objetos que pueden enviar mensajes. Cada actor tiene una "bandeja de entrada" o buzón, donde llegan los mensajes, que son representados como una cola. Puede trabajar secuencialmente la cola de mensajes en su bandeja de entrada, o realizar una búsqueda de patrones en los mensajes.

Para cada articulo comercializable hay un actor subastador que publica información sobre el articulo, se encarga de aceptar las ofertas de los clientes y de comunicarse con el vendedor y el comprador ganador para cerrar la transacción. Presentaremos aquí la visión general de una implementación simple.

Como primer paso, se definen los mensajes que se intercambian durante una subasta. Hay dos clases abstractas base: AuctionMessage para los mensajes de los clientes con el servicio de subastas, y AuctionReply para las respuestas del servicio a los clientes. Para ambas clases base existe un número de casos, que se definen en la Figura 3.1

Para cada clase base, hay una serie de *case classes* que definen el formato de los mensajes particulares de la clase. Estos mensajes también pueden ser asignados finalmente a pequeños documentos XML. Suponemos la existencia de herramientas automáticas para la conversión entre documentos XML y estructuras de datos internas como las definidas anteriormente.

La Figura 3.2 presenta la implementación en Scala de una clase Auction para actores de subastas que coordinan la oferta en un artículo. Los objetos de esta clase se crean mediante la indicación de

```
import scala.actors.Actor
abstract class AuctionMessage
case class Offer(bid: Int, client: Actor) extends AuctionMessage
case class Inquire(client: Actor)
                                           extends AuctionMessage
abstract class AuctionReply
case class Status(asked: Int, expire: Date) extends AuctionReply
case object BestOffer
                                             extends AuctionReply
case class BeatenOffer(maxBid: Int)
                                             extends AuctionReply
case class AuctionConcluded(seller: Actor, client: Actor)
                                             extends AuctionReply
case object AuctionFailed
                                             extends AuctionReply
case object AuctionOver
                                             extends AuctionReply
```

Listing 3.1: Clases de mensajes para un servicio de Subastas.

- un actor "vendedor" (*seller* en inglés) que debe ser notificado cuando la subasta haya terminado,
- una oferta mínima.
- la fecha en que la subasta cerrará.

El comportamiento del actor es definido por su método act. Este método selecciona repetidas veces (usando receiveWithin) un mensaje y reacciona según su tipo, hasta que la subasta se cierra, que es señalado por un mensaje TIMEOUT. Antes de detenerse completamente, se mantiene activo durante un nuevo período determinado por la constante timeToShutdown y responde a las ofertas con que la subasta ya se ha cerrado.

Aquí está la explicación más detallada de los constructos utilizados en este programa:

- El método receiveWithin de la clase Actor toma como parámetros un período de tiempo determinado en milisegundos y una función que procesa los mensajes en el buzón (bandeja de entrada). La función, está dada por una serie de casos que especifican cada patrón y una acción a realizar según el patrón con el que coincida el mensaje. El método receiveWithin selecciona el primer mensaje en el buzón que coincide con uno de estos patrones y le aplica la acción que corresponde.
- El último caso de receiveWithin está definido por el patrón TIMEOUT. Si no se reciben otros mensajes mientras tanto, este patrón se activa después del tiempo que se pasa como argumento al método receiveWithin. TIMEOUT es un mensaje especial, que se activa por la misma implementación del Actor.

```
class Auction(seller: Actor, minBid: Int, closing: Date) extends Actor {
 val timeToShutdown = 36000000 // milisegundos
  val bidIncrement = 10
 def act() {
    var maxBid = minBid - bidIncrement
   var maxBidder: Actor = null
    var running = true
    while (running) {
      receiveWithin ((closing.getTime() - new Date().getTime())) {
        case Offer(bid, client) =>
          if (bid >= maxBid + bidIncrement) {
            if (maxBid >= minBid) maxBidder ! BeatenOffer(bid)
            maxBid = bid; maxBidder = client; client ! BestOffer
          } else {
            client ! BeatenOffer(maxBid)
          }
        case Inquire(client) =>
          client ! Status(maxBid, closing)
        case TIMEOUT =>
          if (maxBid >= minBid) {
            val reply = AuctionConcluded(seller, maxBidder)
            maxBidder ! reply; seller ! reply
          } else {
            seller! AuctionFailed
          receiveWithin(timeToShutdown) {
            case Offer(_, client) => client ! AuctionOver
            case TIMEOUT => running = false
          }
      }
   }
 }
}
```

Listing 3.2: Implementación de un servicio de subastas.

■ Los mensajes de respuesta se envían utilizando la sintaxis de la forma destino! UnMensaje.! Se utiliza aquí como un operador binario, con un actor y un mensaje como argumentos. Esto en Scala es equivalente a la llamada de métodos destino.!(UnMensaje), es decir, la invocación del método! del actor llamado "destino", con algún mensaje dado como parámetro.

La discusión anterior da una degustación de la programación distribuida en Scala. Podría parecer que Scala posee un rico conjunto de constructos del lenguaje que apoyan los procedimientos con actores, el envío y recepción de mensaje, programación con tiempos de espera, etc. De hecho, es todo lo contrario. Todos los constructos de lo discutido arriba se ofrecen como métodos en la biblioteca de clases Actor. Esta clase está implementada en Scala, basadose en el modelo hilo conductor(en inglés, *underlying thread model*) de la lengua huésped (por ejemplo, Java o .NET¹). La aplicación de todas las características de la clase Actor se verán más adelante en la sección 17.11

Las ventajas del enfoque basado en bibliotecas, son la sencillez relativa del núcleo del lenguaje y la flexibilidad para quienes diseñan bibliotecas. Debido a que no es necesario especificar los detalles del proceso de comunicación de alto nivel el núcleo del lenguaje, este se puede mantener más simple y más general. Debido a que el particular modelo de los mensajes en un buzón(bandeja de entrada) es un módulo de una biblioteca, este puede ser modificado libremente si se hace necesario un modelo diferente en alguna aplicación. El enfoque requiere sin embargo que el núcleo del lenguaje sea lo suficientemente expresivo como para proporcionar las abstracciones lingüísticas necesarias en una forma conveniente. Scala ha sido diseñado con esto en mente, uno de los principales objetivos en su diseño es que debe ser lo suficientemente flexible para actuar como un idioma práctico para acoger lenguajes de dominio específico aplicados mediante módulos de biblioteca. Por ejemplo, los constructos de comunicación del actor presentado anteriormente, puede considerarse como un lenguaje de dominio específico de ese tipo, que conceptualmente extiende el núcleo Scala.

<sup>&</sup>lt;sup>1</sup>Aunque el compilador oficial de Scala está escrito en Java para ser usado con la JMV, existe una versión escrita en C# para la plataforma .NET; cabe anotar, que es una versión desactualizada del lenguaje Scala.

### Chapter 4

## **Expreciones y Funciones Simples**

Los ejemplos anteriores dan una impresión de lo que se puede hacer con Scala. Ahora introduciremos los constructos uno por uno de una manera más sistemática. Comenzamos con el nivel más pequeño, las expresiones y las funciones.

#### 4.1 Expreciones y Funciones Simples

Scala viene con un intérprete que puede ser visto como una calculadora de lujo (Esto será común a programadores que conzcan Python o Ruby, que son lenguajes que también vienen con interprete). El usuario interactúa con la calculadora, escribiendo expresiones. La calculadora devuelve los resultados de la evaluación y sus tipos. Por ejemplo:

```
scala> 87 + 145
unnamed0: Int = 232

scala> 5 + 2 * 3
unnamed1: Int = 11

scala> "hola" + " mundo!"
unnamed2: java.lang.String = hola mundo!
```

También es posible nombrar una sub-expresión y después usar su nombre en lugar de la expresión:

```
scala> def scale = 5
scale: Int
scala> 7 * scale
unnamed3: Int = 35
```

```
scala> def pi = 3.141592653589793
pi: Double

scala> def radio = 10
radio: Int

scala> 2 * pi * radio
unnamed4: Double = 62.83185307179586
```

Las definiciones comienzan con la palabra reservada **def**; esto asigna un nombre que hace de sinónimo de la expresión que va despues del signo =. El intérprete responderá con el nombre asignado y su tipo.

Al ejecutar una definición como **def** x = e no se evaluará la expresión e. En su lugar, e se evalúa cada vez que x se utiliza. Por otra parte, Scala ofrece otro estilo de definición: **val** x = e, que evalúa el lado derecho e como parte de la evaluación de la definición. Si x se utiliza posteriormente, es inmediatamente sustituido por el valor pre-computado de e, por lo que la expresión no tiene que ser evaluada de nuevo.

¿Cómo son evaluadas las expresiones? Una expresión consta de operadores y operandos, y se evalúa en repetidas ocasiones aplicando siguientes medidas simplificadas.

- Seleccionar la operación más a la izquierda
- evaluar esos operandos
- aplicar el operador a los valores operandos.

Un nombre definido por **def** se evalúa sustituyendo el nombre por la definición (sin evaluar) de la mano derecha. Un nombre definido por **val** se evalúa sustituyendo el nombre por el valor de la definición de la mano derecha. El proceso de evaluación se detiene una vez que han alcanzado un valor. Un valor es un elemento de datos como una cadena, un número, una matriz, o una lista.

Example 4.1.1 Aquí hay una evaluación de una expresión aritmética.

```
(2 * pi) * radio

→ (2 * 3.141592653589793) * radio

→ 6.283185307179586 * radio

→ 6.283185307179586 * 10

→ 62.83185307179586
```

El proceso de simplificación gradual de las expresiones a valores se conoce como *reducción*.

4.2 Parámetros 15

#### 4.2 Parámetros

Usando **def**, también es posible definir funciones con parámetros. Por ejemplo:

```
scala> def square(x: Double) = x * x
square: (Double)Double

scala> square(2)
unnamed0: Double = 4.0

scala> square(5 + 3)
unnamed1: Double = 64.0

scala> square(square(4))
unnamed2: Double = 256.0

scala> def sumOfSquares(x: Double, y: Double) = square(x) + square(y)
sumOfSquares: (Double,Double)Double

scala> sumOfSquares(3, 2 + 2)
unnamed3: Double = 25.0
```

Los parámetros de una función van despues de su nombre y están siempre entre paréntesis. Todos los parámetros viene con un tipo, que se indica a continuación del nombre del parámetro y dos puntos (:).

Las funciones con parámetros se evalúan de forma análoga a los operadores en las expresiones. En primer lugar, los argumentos de la función se evalúan (en orden de izquierda a derecha). A continuación, la función aplicada se sustituye por las funciónes que están a su lado derecho, y al mismo tiempo todos los parámetros formales de la función son reemplazados por sus argumentos reales correspondientes.

#### **Example 4.2.1**

```
sumOfSquares(3, 2+2)

→ sumOfSquares(3, 4)

→ square(3) + square(4)

→ 3 * 3 + square(4)

→ 9 + square(4)

→ 9 + 4 * 4

→ 9 + 16

→ 25
```

The example shows that the interpreter reduces function arguments to values before rewriting the function application. One could instead have chosen to apply the function to unreduced arguments. This would have yielded the following reduction sequence:

```
sumOfSquares(3, 2+2)

→ square(3) + square(2+2)

→ 3 * 3 + square(2+2)

→ 9 + square(2+2)

→ 9 + (2+2) * (2+2)

→ 9 + 4 * (2+2)

→ 9 + 4 * 4

→ 9 + 16

→ 25
```

The second evaluation order is known as *call-by-name*, whereas the first one is known as *call-by-value*. For expressions that use only pure functions and that therefore can be reduced with the substitution model, both schemes yield the same final values.

Call-by-value has the advantage that it avoids repeated evaluation of arguments. Call-by-name has the advantage that it avoids evaluation of arguments when the parameter is not used at all by the function. Call-by-value is usually more efficient than call-by-name, but a call-by-value evaluation might loop where a call-by-name evaluation would terminate. Consider:

```
scala> def loop: Int = loop
loop: Int
scala> def first(x: Int, y: Int) = x
first: (Int,Int)Int
```

Then first(1, loop) reduces with call-by-name to 1, whereas the same term reduces with call-by-value repeatedly to itself, hence evaluation does not terminate.

```
first(1, loop)

→ first(1, loop)

→ first(1, loop)

→ ...
```

Scala uses call-by-value by default, but it switches to call-by-name evaluation if the parameter type is preceded by =>.

#### **Example 4.2.2**

```
scala> def constOne(x: Int, y: => Int) = 1
constOne: (Int,=> Int)Int

scala> constOne(1, loop)
unnamedO: Int = 1

scala> constOne(loop, 2)  // gives an infinite loop.
```

^C // stops execution with Ctrl-C

#### 4.3 Conditional Expressions

Scala's **if-else** lets one choose between two alternatives. Its syntax is like Java's **if-else**. But where Java's **if-else** can be used only as an alternative of statements, Scala allows the same syntax to choose between two expressions. That's why Scala's **if-else** serves also as a substitute for Java's conditional expression ...? ...:

#### Example 4.3.1

```
scala> def abs(x: Double) = if (x >= 0) x else -x abs: (Double)Double
```

Scala's boolean expressions are similar to Java's; they are formed from the constants **true** and **false**, comparison operators, boolean negation! and the boolean operators && and ||.

#### 4.4 Example: Square Roots by Newton's Method

We now illustrate the language elements introduced so far in the construction of a more interesting program. The task is to write a function

```
def sqrt(x: Double): Double = ...
```

which computes the square root of x.

A common way to compute square roots is by Newton's method of successive approximations. One starts with an initial guess y (say: y = 1). One then repeatedly improves the current guess y by taking the average of y and x/y. As an example, the next three columns indicate the guess y, the quotient x/y, and their average for the first approximations of  $\sqrt{2}$ .

One can implement this algorithm in Scala by a set of small functions, which each represent one of the elements of the algorithm.

We first define a function for iterating from a guess to the result:

```
def sqrtIter(guess: Double, x: Double): Double =
  if (isGoodEnough(guess, x)) guess
  else sqrtIter(improve(guess, x), x)
```

Note that sqrtIter calls itself recursively. Loops in imperative programs can always be modeled by recursion in functional programs.

Note also that the definition of sqrtIter contains a return type, which follows the parameter section. Such return types are mandatory for recursive functions. For a non-recursive function, the return type is optional; if it is missing the type checker will compute it from the type of the function's right-hand side. However, even for non-recursive functions it is often a good idea to include a return type for better documentation.

As a second step, we define the two functions called by sqrtIter: a function to improve the guess and a termination test isGoodEnough. Here is their definition.

```
def improve(guess: Double, x: Double) =
   (guess + x / guess) / 2

def isGoodEnough(guess: Double, x: Double) =
   abs(square(guess) - x) < 0.001</pre>
```

Finally, the sqrt function itself is defined by an application of sqrtIter.

```
def sqrt(x: Double) = sqrtIter(1.0, x)
```

**Exercise 4.4.1** The isGoodEnough test is not very precise for small numbers and might lead to non-termination for very large ones (why?). Design a different version of isGoodEnough which does not have these problems.

**Exercise 4.4.2** Trace the execution of the sqrt(4) expression.

#### 4.5 Nested Functions

The functional programming style encourages the construction of many small helper functions. In the last example, the implementation of sqrt made use of the helper functions sqrtIter, improve and isGoodEnough. The names of these functions are relevant only for the implementation of sqrt. We normally do not want users of sqrt to access these functions directly.

We can enforce this (and avoid name-space pollution) by including the helper functions within the calling function itself:

```
def sqrt(x: Double) = {
  def sqrtIter(guess: Double, x: Double): Double =
```

4.5 Nested Functions 19

```
if (isGoodEnough(guess, x)) guess
  else sqrtIter(improve(guess, x), x)
def improve(guess: Double, x: Double) =
    (guess + x / guess) / 2
def isGoodEnough(guess: Double, x: Double) =
    abs(square(guess) - x) < 0.001
sqrtIter(1.0, x)
}</pre>
```

In this program, the braces { . . . } enclose a *block*. Blocks in Scala are themselves expressions. Every block ends in a result expression which defines its value. The result expression may be preceded by auxiliary definitions, which are visible only in the block itself.

Every definition in a block must be followed by a semicolon, which separates this definition from subsequent definitions or the result expression. However, a semicolon is inserted implicitly at the end of each line, unless one of the following conditions is true.

- 1. Either the line in question ends in a word such as a period or an infix-operator which would not be legal as the end of an expression.
- 2. Or the next line begins with a word that cannot start a expression.
- 3. Or we are inside parentheses (...) or brackets, because these cannot contain multiple statements anyway.

Therefore, the following are all legal:

Scala uses the usual block-structured scoping rules. A name defined in some outer block is visible also in some inner block, provided it is not redefined there. This rule permits us to simplify our sqrt example. We need not pass x around as an additional parameter of the nested functions, since it is always visible in them as a parameter of the outer function sqrt. Here is the simplified code:

```
def sqrt(x: Double) = {
  def sqrtIter(guess: Double): Double =
    if (isGoodEnough(guess)) guess
    else sqrtIter(improve(guess))
  def improve(guess: Double) =
      (guess + x / guess) / 2
  def isGoodEnough(guess: Double) =
    abs(square(guess) - x) < 0.001
  sqrtIter(1.0)
}</pre>
```

#### 4.6 Tail Recursion

Consider the following function to compute the greatest common divisor of two given numbers.

```
def gcd(a: Int, b: Int): Int = if (b == 0) a else gcd(b, a % b)
```

Using our substitution model of function evaluation, gcd(14, 21) evaluates as follows:

```
gcd(14, 21)

→ if (21 == 0) 14 else gcd(21, 14 % 21)

→ if (false) 14 else gcd(21, 14 % 21)

→ gcd(21, 14 % 21)

→ gcd(21, 14)

→ if (14 == 0) 21 else gcd(14, 21 % 14)

→ gcd(14, 21 % 14)

→ gcd(14, 7)

→ if (7 == 0) 14 else gcd(7, 14 % 7)

→ gcd(7, 14 % 7)

→ gcd(7, 0)

→ if (0 == 0) 7 else gcd(0, 7 % 0)

→ → 7
```

Contrast this with the evaluation of another recursive function, factorial:

```
def factorial(n: Int): Int = if (n == 0) 1 else n * factorial(n - 1)
```

4.6 Tail Recursion 21

The application factorial(5) rewrites as follows:

```
factorial(5)

→ if (5 == 0) 1 else 5 * factorial(5 - 1)

→ 5 * factorial(5 - 1)

→ 5 * factorial(4)

→ ... → 5 * (4 * factorial(3))

→ ... → 5 * (4 * (3 * factorial(2)))

→ ... → 5 * (4 * (3 * (2 * factorial(1))))

→ ... → 5 * (4 * (3 * (2 * (1 * factorial(0))))

→ ... → 5 * (4 * (3 * (2 * (1 * 1))))

→ ... → 5 * (4 * (3 * (2 * (1 * 1))))
```

There is an important difference between the two rewrite sequences: The terms in the rewrite sequence of gcd have again and again the same form. As evaluation proceeds, their size is bounded by a constant. By contrast, in the evaluation of factorial we get longer and longer chains of operands which are then multiplied in the last part of the evaluation sequence.

Even though actual implementations of Scala do not work by rewriting terms, they nevertheless should have the same space behavior as in the rewrite sequences. In the implementation of gcd, one notes that the recursive call to gcd is the last action performed in the evaluation of its body. One also says that gcd is "tail-recursive". The final call in a tail-recursive function can be implemented by a jump back to the beginning of that function. The arguments of that call can overwrite the parameters of the current instantiation of gcd, so that no new stack space is needed. Hence, tail recursive functions are iterative processes, which can be executed in constant space.

By contrast, the recursive call in factorial is followed by a multiplication. Hence, a new stack frame is allocated for the recursive instance of factorial, and is deallocated after that instance has finished. The given formulation of the factorial function is not tail-recursive; it needs space proportional to its input parameter for its execution.

More generally, if the last action of a function is a call to another (possibly the same) function, only a single stack frame is needed for both functions. Such calls are called "tail calls". In principle, tail calls can always re-use the stack frame of the calling function. However, some run-time environments (such as the Java VM) lack the primitives to make stack frame re-use for tail calls efficient. A production quality Scala implementation is therefore only required to re-use the stack frame of a directly tail-recursive function whose last action is a call to itself. Other tail calls might be optimized also, but one should not rely on this across implementations.

**Exercise 4.6.1** Design a tail-recursive version of factorial.

### Chapter 5

## **First-Class Functions**

A function in Scala is a "first-class value". Like any other value, it may be passed as a parameter or returned as a result. Functions which take other functions as parameters or return them as results are called *higher-order* functions. This chapter introduces higher-order functions and shows how they provide a flexible mechanism for program composition.

As a motivating example, consider the following three related tasks:

1. Write a function to sum all integers between two given numbers a and b:

```
def sumInts(a: Int, b: Int): Int =
  if (a > b) 0 else a + sumInts(a + 1, b)
```

2. Write a function to sum the squares of all integers between two given numbers a and b:

```
def square(x: Int): Int = x * x
def sumSquares(a: Int, b: Int): Int =
  if (a > b) 0 else square(a) + sumSquares(a + 1, b)
```

3. Write a function to sum the powers  $2^n$  of all integers n between two given numbers a and b:

```
def powerOfTwo(x: Int): Int = if (x == 0) 1 else 2 * powerOfTwo(x - 1)
def sumPowersOfTwo(a: Int, b: Int): Int =
  if (a > b) 0 else powerOfTwo(a) + sumPowersOfTwo(a + 1, b)
```

These functions are all instances of  $\sum_{a}^{b} f(n)$  for different values of f. We can factor out the common pattern by defining a function sum:

```
def sum(f: Int => Int, a: Int, b: Int): Int =
  if (a > b) 0 else f(a) + sum(f, a + 1, b)
```

24 First-Class Functions

The type Int => Int is the type of functions that take arguments of type Int and return results of type Int. So sum is a function which takes another function as a parameter. In other words, sum is a *higher-order* function.

Using sum, we can formulate the three summing functions as follows.

```
def sumInts(a: Int, b: Int): Int = sum(id, a, b)
  def sumSquares(a: Int, b: Int): Int = sum(square, a, b)
  def sumPowersOfTwo(a: Int, b: Int): Int = sum(powerOfTwo, a, b)

where

def id(x: Int): Int = x
  def square(x: Int): Int = x * x
  def powerOfTwo(x: Int): Int = if (x == 0) 1 else 2 * powerOfTwo(x - 1)
```

#### 5.1 Anonymous Functions

Parameterization by functions tends to create many small functions. In the previous example, we defined id, square and power as separate functions, so that they could be passed as arguments to sum.

Instead of using named function definitions for these small argument functions, we can formulate them in a shorter way as *anonymous functions*. An anonymous function is an expression that evaluates to a function; the function is defined without giving it a name. As an example consider the anonymous square function:

```
(x: Int) \Rightarrow x * x
```

The part before the arrow '=>' are the parameters of the function, whereas the part following the '=>' is its body. For instance, here is an anonymous function which multiples its two arguments.

```
(x: Int, y: Int) \Rightarrow x * y
```

Using anonymous functions, we can reformulate the first two summation functions without named auxiliary functions:

```
def sumInts(a: Int, b: Int): Int = sum((x: Int) => x, a, b)
def sumSquares(a: Int, b: Int): Int = sum((x: Int) => x * x, a, b)
```

Often, the Scala compiler can deduce the parameter type(s) from the context of the anonymous function in which case they can be omitted. For instance, in the case of sumInts or sumSquares, one knows from the type of sum that the first parameter must be a function of type Int => Int. Hence, the parameter type Int is redundant and may be omitted. If there is a single parameter without a type, we may also omit

5.2 Currying 25

the parentheses around it:

```
def sumInts(a: Int, b: Int): Int = sum(x => x, a, b)
def sumSquares(a: Int, b: Int): Int = sum(x => x * x, a, b)
```

Generally, the Scala term  $(x_1: T_1, \ldots, x_n: T_n) \Rightarrow$  E defines a function which maps its parameters  $x_1, \ldots, x_n$  to the result of the expression E (where E may refer to  $x_1, \ldots, x_n$ ). Anonymous functions are not essential language elements of Scala, as they can always be expressed in terms of named functions. Indeed, the anonymous function

```
(x_1: T_1, \ldots, x_n: T_n) \Rightarrow E
```

is equivalent to the block

```
{ def f (x_1: T_1, ..., x_n: T_n) = E ; f_ }
```

where f is fresh name which is used nowhere else in the program. We also say, anonymous functions are "syntactic sugar".

#### 5.2 Currying

The latest formulation of the summing functions is already quite compact. But we can do even better. Note that a and b appear as parameters and arguments of every function but they do not seem to take part in interesting combinations. Is there a way to get rid of them?

Let's try to rewrite sum so that it does not take the bounds a and b as parameters:

```
def sum(f: Int => Int): (Int, Int) => Int = {
  def sumF(a: Int, b: Int): Int =
    if (a > b) 0 else f(a) + sumF(a + 1, b)
    sumF
}
```

In this formulation, sum is a function which returns another function, namely the specialized summing function sumF. This latter function does all the work; it takes the bounds a and b as parameters, applies sum's function parameter f to all integers between them, and sums up the results.

Using this new formulation of sum, we can now define:

```
def sumInts = sum(x => x)
def sumSquares = sum(x => x * x)
def sumPowersOfTwo = sum(powerOfTwo)
```

Or, equivalently, with value definitions:

26 First-Class Functions

```
val sumInts = sum(x => x)
val sumSquares = sum(x => x * x)
val sumPowersOfTwo = sum(powerOfTwo)
```

sumInts, sumSquares, and sumPowersOfTwo can be applied like any other function. For instance,

```
scala> sumSquares(1, 10) + sumPowersOfTwo(10, 20)
unnamed0: Int = 2096513
```

How are function-returning functions applied? As an example, in the expression

```
sum(x => x * x)(1, 10),
```

the function sum is applied to the squaring function  $(x \Rightarrow x * x)$ . The resulting function is then applied to the second argument list, (1, 10).

This notation is possible because function application associates to the left. That is, if args<sub>1</sub> and args<sub>2</sub> are argument lists, then

```
f(args_1)(args_2) is equivalent to (f(args_1))(args_2)
```

In our example, sum(x => x \* x)(1, 10) is equivalent to the following expression: (sum(x => x \* x))(1, 10).

The style of function-returning functions is so useful that Scala has special syntax for it. For instance, the next definition of sum is equivalent to the previous one, but is shorter:

```
def sum(f: Int => Int)(a: Int, b: Int): Int =
  if (a > b) 0 else f(a) + sum(f)(a + 1, b)
```

Generally, a curried function definition

```
def f (args<sub>1</sub>) ... (args<sub>n</sub>) = E
```

where n > 1 expands to

```
def f (args<sub>1</sub>) ... (args<sub>n-1</sub>) = { def g (args<sub>n</sub>) = E ; g }
```

where g is a fresh identifier. Or, shorter, using an anonymous function:

```
def f (args<sub>1</sub>) ... (args<sub>n-1</sub>) = ( args<sub>n</sub> ) \Rightarrow E .
```

Performing this step n times yields that

```
def f (args<sub>1</sub>) ... (args<sub>n</sub>) = E
```

is equivalent to

```
def f = (args_1) \Rightarrow \dots \Rightarrow (args_n) \Rightarrow E.
```

Or, equivalently, using a value definition:

```
val f = (args_1) \Rightarrow \dots \Rightarrow (args_n) \Rightarrow E.
```

This style of function definition and application is called *currying* after its promoter, Haskell B. Curry, a logician of the 20th century, even though the idea goes back further to Moses Schönfinkel and Gottlob Frege.

The type of a function-returning function is expressed analogously to its parameter list. Taking the last formulation of sum as an example, the type of sum is (Int => Int) => (Int, Int) => Int. This is possible because function types associate to the right. I.e.

```
T_1 \Rightarrow T_2 \Rightarrow T_3 is equivalent to T_1 \Rightarrow (T_2 \Rightarrow T_3)
```

**Exercise 5.2.1** 1. The sum function uses a linear recursion. Can you write a tail-recursive one by filling in the ??'s?

```
def sum(f: Int => Int)(a: Int, b: Int): Int = {
    def iter(a: Int, result: Int): Int = {
        if (??) ??
        else iter(??, ??)
    }
    iter(??, ??)
}
```

**Exercise 5.2.2** Write a function product that computes the product of the values of functions at points over a given range.

**Exercise 5.2.3** Write factorial in terms of product.

**Exercise 5.2.4** Can you write an even more general function which generalizes both sum and product?

#### 5.3 Example: Finding Fixed Points of Functions

A number x is called a *fixed point* of a function f if

```
f(x) = x.
```

For some functions f we can locate the fixed point by beginning with an initial guess and then applying f repeatedly, until the value does not change anymore (or the change is within a small tolerance). This is possible if the sequence

28 First-Class Functions

```
x, f(x), f(f(x)), f(f(f(x))), ...
```

converges to fixed point of f. This idea is captured in the following "fixed-point finding function":

```
val tolerance = 0.0001
def isCloseEnough(x: Double, y: Double) = abs((x - y) / x) < tolerance
def fixedPoint(f: Double => Double)(firstGuess: Double) = {
    def iterate(guess: Double): Double = {
        val next = f(guess)
        if (isCloseEnough(guess, next)) next
        else iterate(next)
    }
    iterate(firstGuess)
}
```

We now apply this idea in a reformulation of the square root function. Let's start with a specification of sqrt:

```
sqrt(x) = the y such that y * y = x
 = the y such that y = x / y
```

Hence, sqrt(x) is a fixed point of the function  $y \Rightarrow x / y$ . This suggests that sqrt(x) can be computed by fixed point iteration:

```
def sqrt(x: double) = fixedPoint(y => x / y)(1.0)
```

But if we try this, we find that the computation does not converge. Let's instrument the fixed point function with a print statement which keeps track of the current guess value:

```
def fixedPoint(f: Double => Double)(firstGuess: Double) = {
  def iterate(guess: Double): Double = {
    val next = f(guess)
    println(next)
    if (isCloseEnough(guess, next)) next
    else iterate(next)
  }
  iterate(firstGuess)
}
```

Then, sqrt(2) yields:

- 2.0
- 1.0
- 2.0
- 1.0
- 2.0

5.4 Summary 29

. . .

One way to control such oscillations is to prevent the guess from changing too much. This can be achieved by *averaging* successive values of the original sequence:

```
scala> def sqrt(x: Double) = fixedPoint(y => (y + x/y) / 2)(1.0)
sqrt: (Double)Double

scala> sqrt(2.0)
    1.5
    1.41666666666665
    1.4142156862745097
    1.4142135623746899
    1.4142135623746899
```

In fact, expanding the fixedPoint function yields exactly our previous definition of fixed point from Section 4.4.

The previous examples showed that the expressive power of a language is considerably enhanced if functions can be passed as arguments. The next example shows that functions which return functions can also be very useful.

Consider again fixed point iterations. We started with the observation that  $\sqrt(x)$  is a fixed point of the function  $y \Rightarrow x / y$ . Then we made the iteration converge by averaging successive values. This technique of *average damping* is so general that it can be wrapped in another function.

```
def averageDamp(f: Double \Rightarrow Double)(x: Double) = (x + f(x)) / 2
```

Using averageDamp, we can reformulate the square root function as follows.

```
def sqrt(x: Double) = fixedPoint(averageDamp(y => x/y))(1.0)
```

This expresses the elements of the algorithm as clearly as possible.

**Exercise 5.3.1** Write a function for cube roots using fixedPoint and averageDamp.

#### 5.4 Summary

We have seen in the previous chapter that functions are essential abstractions, because they permit us to introduce general methods of computing as explicit, named elements in our programming language. The present chapter has shown that these abstractions can be combined by higher-order functions to create further abstractions. As programmers, we should look out for opportunities to abstract and to reuse. The highest possible level of abstraction is not always the best, but it is important to know abstraction techniques, so that one can use abstractions where appropriate.

30 First-Class Functions

#### 5.5 Language Elements Seen So Far

Chapters 4 and 5 have covered Scala's language elements to express expressions and types comprising of primitive data and functions. The context-free syntax of these language elements is given below in extended Backus-Naur form, where '|' denotes alternatives, [...] denotes option (0 or 1 occurrence), and {...} denotes repetition (0 or more occurrences).

#### Characters

Scala programs are sequences of (Unicode) characters. We distinguish the following character sets:

```
• whitespace, such as '', tabulator, or newline characters,
```

```
letters 'a' to 'z', 'A' to 'Z',
```

```
digits '0' to '9',
```

the delimiter characters

```
. , ; ( ) { } [ ] \ " '
```

• operator characters, such as '#' '+', ':'. Essentially, these are printable characters which are in none of the character sets above.

#### Lexemes:

Literals are as in Java. They define numbers, characters, strings, or boolean values. Examples of literals as 0, 1.0e10, 'x', he said hi!"", or **true**.

Identifiers can be of two forms. They either start with a letter, which is followed by a (possibly empty) sequence of letters or symbols, or they start with an operator character, which is followed by a (possibly empty) sequence of operator characters. Both forms of identifiers may contain underscore characters '\_'. Furthermore, an underscore character may be followed by either sort of identifier. Hence, the following are all legal identifiers:

```
x Room10a + -- foldl_: +_vector
```

It follows from this rule that subsequent operator-identifiers need to be separated by whitespace. For instance, the input x+-y is parsed as the three token sequence x,

+-, y. If we want to express the sum of x with the negated value of y, we need to add at least one space, e.g. x+-y.

The \$ character is reserved for compiler-generated identifiers; it should not be used in source programs.

The following are reserved words, they may not be used as identifiers:

| abstract | case    | catch     | class    | def      |
|----------|---------|-----------|----------|----------|

## Chapter 6

## **Classes and Objects**

Scala does not have a built-in type of rational numbers, but it is easy to define one, using a class. Here's a possible implementation.

```
class Rational(n: Int, d: Int) {
 private def gcd(x: Int, y: Int): Int = {
    if (x == 0) v
    else if (x < 0) gcd(-x, y)
    else if (y < 0) -gcd(x, -y)
    else gcd(y % x, x)
 private val g = gcd(n, d)
 val numer: Int = n/g
 val denom: Int = d/g
 def +(that: Rational) =
    new Rational(numer * that.denom + that.numer * denom,
                 denom * that.denom)
 def -(that: Rational) =
   new Rational(numer * that.denom - that.numer * denom,
                 denom * that.denom)
 def *(that: Rational) =
   new Rational(numer * that.numer, denom * that.denom)
 def /(that: Rational) =
   new Rational(numer * that.denom, denom * that.numer)
}
```

This defines Rational as a class which takes two constructor arguments n and d, containing the number's numerator and denominator parts. The class provides fields which return these parts as well as methods for arithmetic over rational numbers. Each arithmetic method takes as parameter the right operand of the operation. The left operand of the operation is always the rational number of which the

method is a member.

**Private members.** The implementation of rational numbers defines a private method gcd which computes the greatest common denominator of two integers, as well as a private field g which contains the gcd of the constructor arguments. These members are inaccessible outside class Rational. They are used in the implementation of the class to eliminate common factors in the constructor arguments in order to ensure that numerator and denominator are always in normalized form.

**Creating and Accessing Objects.** As an example of how rational numbers can be used, here's a program that prints the sum of all numbers 1/i where i ranges from 1 to 10.

```
var i = 1
var x = new Rational(0, 1)
while (i <= 10) {
    x += new Rational(1, i)
    i += 1
}
println("" + x.numer + "/" + x.denom)</pre>
```

The + takes as left operand a string and as right operand a value of arbitrary type. It returns the result of converting its right operand to a string and appending it to its left operand.

**Inheritance and Overriding.** Every class in Scala has a superclass which it extends. If a class does not mention a superclass in its definition, the root type scala. AnyRef is implicitly assumed (for Java implementations, this type is an alias for java.lang.Object. For instance, class Rational could equivalently be defined as

```
class Rational(n: Int, d: Int) extends AnyRef {
    ... // as before
}
```

A class inherits all members from its superclass. It may also redefine (or: *override*) some inherited members. For instance, class java.lang.Object defines a method toString which returns a representation of the object as a string:

```
class Object {
    ...
  def toString: String = ...
}
```

The implementation of toString in Object forms a string consisting of the object's class name and a number. It makes sense to redefine this method for objects that are rational numbers:

```
class Rational(n: Int, d: Int) extends AnyRef {
    ... // as before
    override def toString = "" + numer + "/" + denom
}
```

Note that, unlike in Java, redefining definitions need to be preceded by an **override** modifier.

If class *A* extends class *B*, then objects of type *A* may be used wherever objects of type *B* are expected. We say in this case that type *A conforms* to type *B*. For instance, Rational conforms to AnyRef, so it is legal to assign a Rational value to a variable of type AnyRef:

```
var x: AnyRef = new Rational(1, 2)
```

**Parameterless Methods.** Unlike in Java, methods in Scala do not necessarily take a parameter list. An example is the square method below. This method is invoked by simply mentioning its name.

```
class Rational(n: Int, d: Int) extends AnyRef {
    ... // as before
    def square = new Rational(numer*numer, denom*denom)
}
val r = new Rational(3, 4)
println(r.square) // prints''9/16''*
```

That is, parameterless methods are accessed just as value fields such as numer are. The difference between values and parameterless methods lies in their definition. The right-hand side of a value is evaluated when the object is created, and the value does not change afterwards. A right-hand side of a parameterless method, on the other hand, is evaluated each time the method is called. The uniform access of fields and parameterless methods gives increased flexibility for the implementer of a class. Often, a field in one version of a class becomes a computed value in the next version. Uniform access ensures that clients do not have to be rewritten because of that change.

**Abstract Classes.** Consider the task of writing a class for sets of integer numbers with two operations, incl and contains. (s incl x) should return a new set which contains the element x together with all the elements of set s. (s contains x) should return true if the set s contains the element x, and should return **false** otherwise. The interface of such sets is given by:

```
abstract class IntSet {
  def incl(x: Int): IntSet
  def contains(x: Int): Boolean
}
```

IntSet is labeled as an *abstract class*. This has two consequences. First, abstract classes may have *deferred* members which are declared but which do not have an implementation. In our case, both incl and contains are such members. Second, because an abstract class might have unimplemented members, no objects of that class may be created using **new**. By contrast, an abstract class may be used as a base class of some other class, which implements the deferred members.

**Traits.** Instead of **abstract class** one also often uses the keyword **trait** in Scala. Traits are abstract classes that are meant to be added to some other class. This might be because a trait adds some methods or fields to an unknown parent class. For instance, a trait Bordered might be used to add a border to a various graphical components. Another usage scenario is where the trait collects signatures of some functionality provided by different classes, much in the way a Java interface would work.

Since IntSet falls in this category, one can alternatively define it as a trait:

```
trait IntSet {
  def incl(x: Int): IntSet
  def contains(x: Int): Boolean
}
```

**Implementing Abstract Classes.** Let's say, we plan to implement sets as binary trees. There are two possible forms of trees. A tree for the empty set, and a tree consisting of an integer and two subtrees. Here are their implementations.

```
class EmptySet extends IntSet {
  def contains(x: Int): Boolean = false
  def incl(x: Int): IntSet = new NonEmptySet(x, new EmptySet, new EmptySet)
}

class NonEmptySet(elem: Int, left: IntSet, right: IntSet) extends IntSet {
  def contains(x: Int): Boolean =
    if (x < elem) left contains x
    else if (x > elem) right contains x
    else true

def incl(x: Int): IntSet =
    if (x < elem) new NonEmptySet(elem, left incl x, right)
    else if (x > elem) new NonEmptySet(elem, left, right incl x)
    else this
```

}

Both EmptySet and NonEmptySet extend class IntSet. This implies that types EmptySet and NonEmptySet conform to type IntSet – a value of type EmptySet or NonEmptySet may be used wherever a value of type IntSet is required.

**Exercise 6.0.1** Write methods union and intersection to form the union and intersection between two sets.

#### Exercise 6.0.2 Add a method

```
def excl(x: Int)
```

to return the given set without the element x. To accomplish this, it is useful to also implement a test method

```
def isEmpty: Boolean
```

for sets.

**Dynamic Binding.** Object-oriented languages (Scala included) use *dynamic dispatch* for method invocations. That is, the code invoked for a method call depends on the run-time type of the object which contains the method. For example, consider the expression s contains 7 where s is a value of declared type s: IntSet. Which code for contains is executed depends on the type of value of s at run-time. If it is an EmptySet value, it is the implementation of contains in class EmptySet that is executed, and analogously for NonEmptySet values. This behavior is a direct consequence of our substitution model of evaluation. For instance,

```
(new EmptySet).contains(7)
```

-> (by replacing *contains* by its body in class *EmptySet*)

false

Or,

```
new NonEmptySet(7, new EmptySet, new EmptySet).contains(1)
```

-> (by replacing *contains* by its body in class *NonEmptySet*)

```
if (1 < 7) new EmptySet contains 1
else if (1 > 7) new EmptySet contains 1
else true
```

-> (by rewriting the conditional)

```
new EmptySet contains 1
```

-> (by replacing *contains* by its body in class *EmptySet*)

false .

Dynamic method dispatch is analogous to higher-order function calls. In both cases, the identity of code to be executed is known only at run-time. This similarity is not just superficial. Indeed, Scala represents every function value as an object (see Section 8.6).

**Objects.** In the previous implementation of integer sets, empty sets were expressed with **new** EmptySet; so a new object was created every time an empty set value was required. We could have avoided unnecessary object creations by defining a value empty once and then using this value instead of every occurrence of **new** EmptySet. For example:

```
val EmptySetVal = new EmptySet
```

One problem with this approach is that a value definition such as the one above is not a legal top-level definition in Scala; it has to be part of another class or object. Also, the definition of class EmptySet now seems a bit of an overkill – why define a class of objects, if we are only interested in a single object of this class? A more direct approach is to use an *object definition*. Here is a more streamlined alternative definition of the empty set:

```
object EmptySet extends IntSet {
  def contains(x: Int): Boolean = false
  def incl(x: Int): IntSet = new NonEmptySet(x, EmptySet, EmptySet)
}
```

The syntax of an object definition follows the syntax of a class definition; it has an optional extends clause as well as an optional body. As is the case for classes, the extends clause defines inherited members of the object whereas the body defines overriding or new members. However, an object definition defines a single object only it is not possible to create other objects with the same structure using **new**. Therefore, object definitions also lack constructor parameters, which might be present in class definitions.

Object definitions can appear anywhere in a Scala program; including at top-level. Since there is no fixed execution order of top-level entities in Scala, one might ask exactly when the object defined by an object definition is created and initialized. The answer is that the object is created the first time one of its members is accessed. This strategy is called *lazy evaluation*.

**Standard Classes.** Scala is a pure object-oriented language. This means that every value in Scala can be regarded as an object. In fact, even primitive types such as int or boolean are not treated specially. They are defined as type aliases of Scala classes in module Predef:

```
type boolean = scala.Boolean
type int = scala.Int
type long = scala.Long
```

For efficiency, the compiler usually represents values of type scala. Int by 32 bit integers, values of type scala. Boolean by Java's booleans, etc. But it converts these specialized representations to objects when required, for instance when a primitive Int value is passed to a function with a parameter of type AnyRef. Hence, the special representation of primitive values is just an optimization, it does not change the meaning of a program.

Here is a specification of class Boolean.

```
package scala
abstract class Boolean {
 def && (x: => Boolean): Boolean
 def || (x: => Boolean): Boolean
  def!
                        : Boolean
                       : Boolean
 def == (x: Boolean)
 def != (x: Boolean) : Boolean
 def < (x: Boolean) : Boolean</pre>
 def > (x: Boolean) : Boolean
 def <= (x: Boolean)</pre>
                       : Boolean
 def >= (x: Boolean)
                      : Boolean
}
```

Booleans can be defined using only classes and objects, without reference to a built-in type of booleans or numbers. A possible implementation of class Boolean is given below. This is not the actual implementation in the standard Scala library. For efficiency reasons the standard implementation uses built-in booleans.

```
package scala
abstract class Boolean {
  def ifThenElse(thenpart: => Boolean, elsepart: => Boolean)

  def && (x: => Boolean): Boolean = ifThenElse(x, false)
  def || (x: => Boolean): Boolean = ifThenElse(true, x)
  def ! : Boolean = ifThenElse(false, true)

  def == (x: Boolean) : Boolean = ifThenElse(x, x.!)
```

def != (x: Boolean)

```
: Boolean = ifThenElse(false, x)
    def < (x: Boolean)</pre>
    def > (x: Boolean)
                         : Boolean = ifThenElse(x.!, false)
    def <= (x: Boolean)</pre>
                         : Boolean = ifThenElse(x, true)
    def >= (x: Boolean)
                         : Boolean = ifThenElse(true, x.!)
  case object True extends Boolean {
    def ifThenElse(t: => Boolean, e: => Boolean) = t
  }
  case object False extends Boolean {
    def ifThenElse(t: => Boolean, e: => Boolean) = e
  }
Here is a partial specification of class Int.
  package scala
  abstract class Int extends AnyVal {
    def toLong: Long
    def toFloat: Float
    def toDouble: Double
    def + (that: Double): Double
    def + (that: Float): Float
    def + (that: Long): Long
    def + (that: Int): Int
                                   // analogous for -, *, /, %
    def << (cnt: Int): Int</pre>
                                   // analogous for >>, >>>
    def & (that: Long): Long
    def & (that: Int): Int
                                   // analogous for /, ^
    def == (that: Double): Boolean
    def == (that: Float): Boolean
    def == (that: Long): Boolean // analogous for !=, <, >, <=, >=
  }
```

: Boolean = ifThenElse(x.!, x)

Class Int can in principle also be implemented using just objects and classes, without reference to a built in type of integers. To see how, we consider a slightly simpler problem, namely how to implement a type Nat of natural (i.e. non-negative) numbers. Here is the definition of an abstract class Nat:

```
abstract class Nat {
  def isZero: Boolean
  def predecessor: Nat
  def successor: Nat
  def + (that: Nat): Nat
  def - (that: Nat): Nat
```

}

To implement the operations of class Nat, we define a sub-object Zero and a subclass Succ (for successor). Each number N is represented as N applications of the Succ constructor to Zero:

```
<u>new Succ( ... new Succ</u> (Zero) ... )
```

The implementation of the Zero object is straightforward:

The implementation of the predecessor and subtraction functions on Zero throws an Error exception, which aborts the program with the given error message.

Here is the implementation of the successor class:

Note the implementation of method successor. To create the successor of a number, we need to pass the object itself as an argument to the Succ constructor. The object itself is referenced by the reserved name **this**.

The implementations of + and - each contain a recursive call with the constructor argument as receiver. The recursion will terminate once the receiver is the Zero object (which is guaranteed to happen eventually because of the way numbers are formed).

**Exercise 6.0.3** Write an implementation Integer of integer numbers The implementation should support all operations of class Nat while adding two methods

```
def isPositive: Boolean
def negate: Integer
```

The first method should return **true** if the number is positive. The second method should negate the number. Do not use any of Scala's standard numeric classes in your implementation. (Hint: There are two possible ways to implement Integer. One can either make use the existing implementation of Nat, representing an integer as a natural number and a sign. Or one can generalize the given implementation of Nat to Integer, using the three subclasses Zero for 0, Succ for positive numbers and Pred for negative numbers.)

### **Language Elements Introduced In This Chapter**

## **Types:**

```
Type = ... | ident
```

Types can now be arbitrary identifiers which represent classes.

### **Expressions:**

```
Expr = ... | Expr '.' ident | 'new' Expr | 'this'
```

An expression can now be an object creation, or a selection E.m of a member m from an object-valued expression E, or it can be the reserved name **this**.

#### **Definitions and Declarations:**

```
Def
            = FunDef | ValDef | ClassDef | TraitDef | ObjectDef
ClassDef
            = ['abstract'] 'class' ident ['(' [Parameters] ')']
               ['extends' Expr] ['{' {TemplateDef} '}']
TraitDef
            = 'trait' ident ['extends' Expr] ['{' {TemplateDef} '}']
            = 'object' ident ['extends' Expr] ['{' {ObjectDef} '}']
ObjectDef
TemplateDef = [Modifier] (Def | Dcl)
ObjectDef
            = [Modifier] Def
Modifier
            = 'private' |
                           'override'
            = FunDcl | ValDcl
Dcl
FunDcl
            = 'def' ident {'(' [Parameters] ')'} ':' Type
            = 'val' ident ':' Type
ValDcl
```

A definition can now be a class, trait or object definition such as

```
class C(params) extends B { defs }
trait T extends B { defs }
object O extends B { defs }
```

The definitions defs in a class, trait or object may be preceded by modifiers **private** or **override**.

Abstract classes and traits may also contain declarations. These introduce *deferred* functions or values with their types, but do not give an implementation. Deferred members have to be implemented in subclasses before objects of an abstract class

or trait can be created.

## Chapter 7

# Case Classes and Pattern Matching

Say, we want to write an interpreter for arithmetic expressions. To keep things simple initially, we restrict ourselves to just numbers and + operations. Such expressions can be represented as a class hierarchy, with an abstract base class Expr as the root, and two subclasses Number and Sum. Then, an expression 1 + (3 + 7) would be represented as

```
new Sum(new Number(1), new Sum(new Number(3), new Number(7)))
```

Now, an evaluator of an expression like this needs to know of what form it is (either Sum or Number) and also needs to access the components of the expression. The following implementation provides all necessary methods.

```
abstract class Expr {
  def isNumber: Boolean
 def isSum: Boolean
 def numValue: Int
 def leftOp: Expr
 def rightOp: Expr
}
class Number(n: Int) extends Expr {
 def isNumber: Boolean = true
  def isSum: Boolean = false
  def numValue: Int = n
 def left0p: Expr = error("Number.left0p")
 def rightOp: Expr = error("Number.rightOp")
class Sum(e1: Expr, e2: Expr) extends Expr {
 def isNumber: Boolean = false
 def isSum: Boolean = true
```

```
def numValue: Int = error("Sum.numValue")
def leftOp: Expr = e1
def rightOp: Expr = e2
}
```

With these classification and access methods, writing an evaluator function is simple:

```
def eval(e: Expr): Int = {
   if (e.isNumber) e.numValue
   else if (e.isSum) eval(e.leftOp) + eval(e.rightOp)
   else error("unrecognized expression kind")
}
```

However, defining all these methods in classes Sum and Number is rather tedious. Furthermore, the problem becomes worse when we want to add new forms of expressions. For instance, consider adding a new expression form Prod for products. Not only do we have to implement a new class Prod, with all previous classification and access methods; we also have to introduce a new abstract method is Product in class Expr and implement that method in subclasses Number, Sum, and Prod. Having to modify existing code when a system grows is always problematic, since it introduces versioning and maintenance problems.

The promise of object-oriented programming is that such modifications should be unnecessary, because they can be avoided by re-using existing, unmodified code through inheritance. Indeed, a more object-oriented decomposition of our problem solves the problem. The idea is to make the "high-level" operation eval a method of each expression class, instead of implementing it as a function outside the expression class hierarchy, as we have done before. Because eval is now a member of all expression nodes, all classification and access methods become superfluous, and the implementation is simplified considerably:

```
abstract class Expr {
  def eval: Int
}
class Number(n: Int) extends Expr {
  def eval: Int = n
}
class Sum(e1: Expr, e2: Expr) extends Expr {
  def eval: Int = e1.eval + e2.eval
}
```

Furthermore, adding a new Prod class does not entail any changes to existing code:

```
class Prod(e1: Expr, e2: Expr) extends Expr {
  def eval: Int = e1.eval * e2.eval
}
```

The conclusion we can draw from this example is that object-oriented decomposition is the technique of choice for constructing systems that should be extensible with new types of data. But there is also another possible way we might want to extend the expression example. We might want to add new *operations* on expressions. For instance, we might want to add an operation that pretty-prints an expression tree to standard output.

If we have defined all classification and access methods, such an operation can easily be written as an external function. Here is an example:

```
def print(e: Expr) {
   if (e.isNumber) Console.print(e.numValue)
   else if (e.isSum) {
      Console.print("(")
      print(e.leftOp)
      Console.print("+")
      print(e.rightOp)
      Console.print(")")
   } else error("unrecognized expression kind")
}
```

However, if we had opted for an object-oriented decomposition of expressions, we would need to add a new print procedure to each class:

```
abstract class Expr {
 def eval: Int
 def print
class Number(n: Int) extends Expr {
 def eval: Int = n
 def print { Console.print(n) }
class Sum(e1: Expr, e2: Expr) extends Expr {
 def eval: Int = e1.eval + e2.eval
 def print {
    Console.print("(")
    print(e1)
    Console.print("+")
    print(e2)
    Console.print(")")
  }
}
```

Hence, classical object-oriented decomposition requires modification of all existing classes when a system is extended with new operations.

As yet another way we might want to extend the interpreter, consider expression simplification. For instance, we might want to write a function which rewrites expressions of the form a \* b + a \* c to a \* (b + c). This operation requires inspection of more than a single node of the expression tree at the same time. Hence, it cannot be implemented by a method in each expression kind, unless that method can also inspect other nodes. So we are forced to have classification and access methods in this case. This seems to bring us back to square one, with all the problems of verbosity and extensibility.

Taking a closer look, one observes that the only purpose of the classification and access functions is to *reverse* the data construction process. They let us determine, first, which sub-class of an abstract base class was used and, second, what were the constructor arguments. Since this situation is quite common, Scala has a way to automate it with case classes.

## 7.1 Case Classes and Case Objects

Case classes and case objects are defined like a normal classes or objects, except that the definition is prefixed with the modifier **case**. For instance, the definitions

```
abstract class Expr
case class Number(n: Int) extends Expr
case class Sum(e1: Expr, e2: Expr) extends Expr
```

introduce Number and Sum as case classes. The **case** modifier in front of a class or object definition has the following effects.

1. Case classes implicitly come with a constructor function, with the same name as the class. In our example, the two functions

```
def Number(n: Int) = new Number(n)
def Sum(e1: Expr, e2: Expr) = new Sum(e1, e2)
```

would be added. Hence, one can now construct expression trees a bit more concisely, as in

```
Sum(Sum(Number(1), Number(2)), Number(3))
```

2. Case classes and case objects implicitly come with implementations of methods toString, equals and hashCode, which override the methods with the same name in class AnyRef. The implementation of these methods takes in each case the structure of a member of a case class into account. The toString method represents an expression tree the way it was constructed. So,

```
Sum(Sum(Number(1), Number(2)), Number(3))
```

would be converted to exactly that string, whereas the default implementation in class AnyRef would return a string consisting of the outermost constructor name Sum and a number. The equals methods treats two case members of a case class as equal if they have been constructed with the same constructor and with arguments which are themselves pairwise equal. This also affects the implementation of == and !=, which are implemented in terms of equals in Scala. So,

```
Sum(Number(1), Number(2)) == Sum(Number(1), Number(2))
```

will yield **true**. If Sum or Number were not case classes, the same expression would be **false**, since the standard implementation of equals in class AnyRef always treats objects created by different constructor calls as being different. The hashCode method follows the same principle as other two methods. It computes a hash code from the case class constructor name and the hash codes of the constructor arguments, instead of from the object's address, which is what the as the default implementation of hashCode does.

3. Case classes implicitly come with nullary accessor methods which retrieve the constructor arguments. In our example, Number would obtain an accessor method

```
def n: Int
```

which returns the constructor parameter n, whereas Sum would obtain two accessor methods

```
def e1: Expr, e2: Expr
```

Hence, if for a value s of type Sum, say, one can now write s.e1, to access the left operand. However, for a value e of type Expr, the term e.e1 would be illegal since e1 is defined in Sum; it is not a member of the base class Expr. So, how do we determine the constructor and access constructor arguments for values whose static type is the base class Expr? This is solved by the fourth and final particularity of case classes.

4. Case classes allow the constructions of *patterns* which refer to the case class constructor.

## 7.2 Pattern Matching

Pattern matching is a generalization of C or Java's switch statement to class hierarchies. Instead of a switch statement, there is a standard method match, which is defined in Scala's root class Any, and therefore is available for all objects. The match method takes as argument a number of cases. For instance, here is an implementation of eval using pattern matching.

```
def eval(e: Expr): Int = e match {
  case Number(n) => n
  case Sum(1, r) => eval(1) + eval(r)
}
```

In this example, there are two cases. Each case associates a pattern with an expression. Patterns are matched against the selector values e. The first pattern in our example, Number(n), matches all values of the form Number(v), where v is an arbitrary value. In that case, the *pattern variable* n is bound to the value v. Similarly, the pattern Sum(1, r) matches all selector values of form  $Sum(v_1, v_2)$  and binds the pattern variables 1 and r to  $v_1$  and  $v_2$ , respectively.

In general, patterns are built from

- Case class constructors, e.g. Number, Sum, whose arguments are again patterns,
- pattern variables, e.g. n, e1, e2,
- the "wildcard" pattern \_,
- literals, e.g. 1, true, .abc",
- constant identifiers, e.g. MAXINT, EmptySet.

Pattern variables always start with a lower-case letter, so that they can be distinguished from constant identifiers, which start with an upper case letter. Each variable name may occur only once in a pattern. For instance, Sum(x, x) would be illegal as a pattern, since the pattern variable x occurs twice in it.

### Meaning of Pattern Matching. A pattern matching expression

```
e match { case p_1 \Rightarrow e_1 \dots case p_n \Rightarrow e_n }
```

matches the patterns  $p_1, ..., p_n$  in the order they are written against the selector value e.

- A constructor pattern  $C(p_1, ..., p_n)$  matches all values that are of type C (or a subtype thereof) and that have been constructed with C-arguments matching patterns  $p_1, ..., p_n$ .
- A variable pattern x matches any value and binds the variable name to that value.
- The wildcard pattern '\_' matches any value but does not bind a name to that value.
- A constant pattern C matches a value which is equal (in terms of ==) to C.

The pattern matching expression rewrites to the right-hand-side of the first case whose pattern matches the selector value. References to pattern variables are replaced by corresponding constructor arguments. If none of the patterns matches, the pattern matching expression is aborted with a MatchError exception.

**Example 7.2.1** Our substitution model of program evaluation extends quite naturally to pattern matching, For instance, here is how eval applied to a simple expression is re-written:

```
eval(Sum(Number(1), Number(2)))
                (by rewriting the application)
->
     Sum(Number(1), Number(2)) match {
         case Number(n) => n
         case Sum(e1, e2) \Rightarrow eval(e1) + eval(e2)
     }
                 (by rewriting the pattern match)
->
     eval(Number(1)) + eval(Number(2))
                (by rewriting the first application)
->
     Number(1) match {
         case Number(n) \Rightarrow n
         case Sum(e1, e2) => eval(e1) + eval(e2)
     } + eval(Number(2))
                 (by rewriting the pattern match)
->
     1 + eval(Number(2))
->* 1 + 2 -> 3
```

**Pattern Matching and Methods.** In the previous example, we have used pattern matching in a function which was defined outside the class hierarchy over which it matches. Of course, it is also possible to define a pattern matching function in that class hierarchy itself. For instance, we could have defined eval is a method of the base class Expr, and still have used pattern matching in its implementation:

```
abstract class Expr {
  def eval: Int = this match {
    case Number(n) => n
    case Sum(e1, e2) => e1.eval + e2.eval
```

```
}
```

**Exercise 7.2.2** Consider the following definitions representing trees of integers. These definitions can be seen as an alternative representation of IntSet:

```
abstract class IntTree
case object EmptyTree extends IntTree
case class Node(elem: Int, left: IntTree, right: IntTree) extends IntTree
```

Complete the following implementations of function contains and insert for IntTree's.

```
def contains(t: IntTree, v: Int): Boolean = t match { ...
    ...
}
def insert(t: IntTree, v: Int): IntTree = t match { ...
    ...
}
```

**Pattern Matching Anonymous Functions.** So far, case-expressions always appeared in conjunction with a match operation. But it is also possible to use case-expressions by themselves. A block of case-expressions such as

```
{ case P_1 \Rightarrow E_1 \dots case P_n \Rightarrow E_n }
```

is seen by itself as a function which matches its arguments against the patterns  $P_1, ..., P_n$ , and produces the result of one of  $E_1, ..., E_n$ . (If no pattern matches, the function would throw a MatchError exception instead). In other words, the expression above is seen as a shorthand for the anonymous function

```
(x \Rightarrow x \text{ match } \{ \text{ case } P_1 \Rightarrow E_1 \dots \text{ case } P_n \Rightarrow E_n \})
```

where x is a fresh variable which is not used otherwise in the expression.

## Chapter 8

## **Generic Types and Methods**

Classes in Scala can have type parameters. We demonstrate the use of type parameters with functional stacks as an example. Say, we want to write a data type of stacks of integers, with methods push, top, pop, and isEmpty. This is achieved by the following class hierarchy:

```
abstract class IntStack {
    def push(x: Int): IntStack = new IntNonEmptyStack(x, this)
    def isEmpty: Boolean
    def top: Int
    def pop: IntStack
}
class IntEmptyStack extends IntStack {
    def isEmpty = true
    def top = error("EmptyStack.top")
    def pop = error("EmptyStack.pop")
}
class IntNonEmptyStack(elem: Int, rest: IntStack) extends IntStack {
    def isEmpty = false
    def top = elem
    def pop = rest
}
```

Of course, it would also make sense to define an abstraction for a stack of Strings. To do that, one could take the existing abstraction for IntStack, rename it to StringStack and at the same time rename all occurrences of type Int to String.

A better way, which does not entail code duplication, is to parameterize the stack definitions with the element type. Parameterization lets us generalize from a specific instance of a problem to a more general one. So far, we have used parameterization only for values, but it is available also for types. To arrive at a *generic* version of Stack, we equip it with a type parameter.

```
abstract class Stack[A] {
    def push(x: A): Stack[A] = new NonEmptyStack[A](x, this)
    def isEmpty: Boolean
    def top: A
    def pop: Stack[A]
}
class EmptyStack[A] extends Stack[A] {
    def isEmpty = true
    def top = error("EmptyStack.top")
    def pop = error("EmptyStack.pop")
}
class NonEmptyStack[A](elem: A, rest: Stack[A]) extends Stack[A] {
    def isEmpty = false
    def top = elem
    def pop = rest
}
```

In the definitions above, 'A' is a *type parameter* of class Stack and its subclasses. Type parameters are arbitrary names; they are enclosed in brackets instead of parentheses, so that they can be easily distinguished from value parameters. Here is an example how the generic classes are used:

```
val x = new EmptyStack[Int]
val y = x.push(1).push(2)
println(y.pop.top)
```

The first line creates a new empty stack of Int's. Note the actual type argument [Int] which replaces the formal type parameter A.

It is also possible to parameterize methods with types. As an example, here is a generic method which determines whether one stack is a prefix of another.

```
def isPrefix[A](p: Stack[A], s: Stack[A]): Boolean = {
  p.isEmpty ||
  p.top == s.top && isPrefix[A](p.pop, s.pop)
}
```

The method parameters are called *polymorphic*. Generic methods are also called *polymorphic*. The term comes from the Greek, where it means "having many forms". To apply a polymorphic method such as isPrefix, we pass type parameters as well as value parameters to it. For instance,

```
val s1 = new EmptyStack[String].push("abc")
val s2 = new EmptyStack[String].push("abx").push(s1.top)
println(isPrefix[String](s1, s2))
```

**Local Type Inference.** Passing type parameters such as [Int] or [String] all the time can become tedious in applications where generic functions are used a lot. Quite often, the information in a type parameter is redundant, because the correct parameter type can also be determined by inspecting the function's value parameters or expected result type. Taking the expression isPrefix[String](s1, s2) as an example, we know that its value parameters are both of type Stack[String], so we can deduce that the type parameter must be String. Scala has a fairly powerful type inferencer which allows one to omit type parameters to polymorphic functions and constructors in situations like these. In the example above, one could have written isPrefix(s1, s2) and the missing type argument [String] would have been inserted by the type inferencer.

## 8.1 Type Parameter Bounds

Now that we know how to make classes generic it is natural to generalize some of the earlier classes we have written. For instance class IntSet could be generalized to sets with arbitrary element types. Let's try. The abstract class for generic sets is easily written.

```
abstract class Set[A] {
  def incl(x: A): Set[A]
  def contains(x: A): Boolean
}
```

However, if we still want to implement sets as binary search trees, we encounter a problem. The contains and incl methods both compare elements using methods < and >. For IntSet this was OK, since type Int has these two methods. But for an arbitrary type parameter a, we cannot guarantee this. Therefore, the previous implementation of, say, contains would generate a compiler error.

One way to solve the problem is to restrict the legal types that can be substituted for type A to only those types that contain methods < and > of the correct types. There is a trait Ordered[A] in the standard class library Scala which represents values which are comparable (via < and >) to values of type A. This trait is defined as follows:

```
/** A class for totally ordered data. */
trait Ordered[A] {

   /** Result of comparing 'this' with operand 'that'.
    * returns 'x' where
    * x < 0 iff this < that</pre>
```

```
# x == 0 iff this == that
# x > 0 iff this > that
#/
def compare(that: A): Int

def < (that: A): Boolean = (this compare that) < 0
def > (that: A): Boolean = (this compare that) > 0
def <= (that: A): Boolean = (this compare that) > 0
def <= (that: A): Boolean = (this compare that) <= 0
def >= (that: A): Boolean = (this compare that) >= 0
def compareTo(that: A): Int = compare(that)
}
```

We can enforce the comparability of a type by demanding that the type is a subtype of Ordered. This is done by giving an upper bound to the type parameter of Set:

```
trait Set[A <: Ordered[A]] {
  def incl(x: A): Set[A]
  def contains(x: A): Boolean
}</pre>
```

The parameter declaration A <: Ordered[A] introduces A as a type parameter which must be a subtype of Ordered[A], i.e. its values must be comparable to values of the same type.

With this restriction, we can now implement the rest of the generic set abstraction as we did in the case of IntSets before.

```
class EmptySet[A <: Ordered[A]] extends Set[A] {
    def contains(x: A): Boolean = false
    def incl(x: A): Set[A] = new NonEmptySet(x, new EmptySet[A], new EmptySet[A])
}

class NonEmptySet[A <: Ordered[A]]
        (elem: A, left: Set[A], right: Set[A]) extends Set[A] {
    def contains(x: A): Boolean =
        if (x < elem) left contains x
        else if (x > elem) right contains x
        else true

def incl(x: A): Set[A] =
    if (x < elem) new NonEmptySet(elem, left incl x, right)
        else if (x > elem) new NonEmptySet(elem, left, right incl x)
        else this
}
```

Note that we have left out the type argument in the object creations **new** NonEmptySet(...). In the same way as for polymorphic methods, missing type arguments in constructor calls are inferred from value arguments and/or the expec-

ted result type.

Here is an example that uses the generic set abstraction. Let's first create a subclass of Ordered, like this:

```
case class Num(value: Double) extends Ordered[Num] {
   def compare(that: Num): Int =
      if (this.value < that.value) -1
      else if (this.value > that.value) 1
      else 0
   }
Then:
   val s = new EmptySet[Num].incl(Num(1.0)).incl(Num(2.0))
   s.contains(Num(1.5))
```

This is OK, as type Num implements the trait Ordered[Num]. However, the following example is in error.

One probem with type parameter bounds is that they require forethought: if we had not declared Num a subclass of Ordered, we would not have been able to use Num elements in sets. By the same token, types inherited from Java, such as Int, Double, or String are not subclasses of Ordered, so values of these types cannot be used as set elements.

A more flexible design, which admits elements of these types, uses *view bounds* instead of the plain type bounds we have seen so far. The only change this entails in the example above is in the type parameters:

```
trait Set[A <% Ordered[A]] ...
class EmptySet[A <% Ordered[A]] ...
class NonEmptySet[A <% Ordered[A]] ...</pre>
```

View bounds <% are weaker than plain bounds <:: A view bounded type parameter clause [A <% T] only specifies that the bounded type A must be *convertible* to the bound type T, using an implicit conversion.

The Scala library predefines implicit conversions for a number of types, including the primitive types and String. Therefore, the redesign set abstraction can be instantiated with these types as well. More explanations on implicit conversions and view bounds are given in Section 15.

## 8.2 Variance Annotations

The combination of type parameters and subtyping poses some interesting questions. For instance, should Stack[String] be a subtype of Stack[AnyRef]? Intuitively, this seems OK, since a stack of Strings is a special case of a stack of AnyRefs. More generally, if T is a subtype of type S then Stack[T] should be a subtype of Stack[S]. This property is called *co-variant* subtyping.

In Scala, generic types have by default non-variant subtyping. That is, with Stack defined as above, stacks with different element types would never be in a subtype relation. However, we can enforce co-variant subtyping of stacks by changing the first line of the definition of class Stack as follows.

```
class Stack[+A] {
```

Prefixing a formal type parameter with a + indicates that subtyping is covariant in that parameter. Besides +, there is also a prefix - which indicates contra-variant subtyping. If Stack was defined **class** Stack[-A] ..., then T a subtype of type S would imply that Stack[S] is a subtype of Stack[T] (which in the case of stacks would be rather surprising!).

In a purely functional world, all types could be co-variant. However, the situation changes once we introduce mutable data. Consider the case of arrays in Java or .NET. Such arrays are represented in Scala by a generic class Array. Here is a partial definition of this class.

```
class Array[A] {
  def apply(index: Int): A
  def update(index: Int, elem: A)
}
```

The class above defines the way Scala arrays are seen from Scala user programs. The Scala compiler will map this abstraction to the underlying arrays of the host system in most cases where this possible.

In Java, arrays are indeed covariant; that is, for reference types T and S, if T is a subtype of S, then also Array[T] is a subtype of Array[S]. This might seem natural but leads to safety problems that require special runtime checks. Here is an example:

In the first line, a new array of strings is created. In the second line, this array is bound to a variable y, of type Array[Any]. Assuming arrays are covariant, this is OK, since Array[String] is a subtype of Array[Any]. Finally, in the last line a rational number is stored in the array. This is also OK, since type Rational is a subtype of

the element type Any of the array y. We thus end up storing a rational number in an array of strings, which clearly violates type soundness.

Java solves this problem by introducing a run-time check in the third line which tests whether the stored element is compatible with the element type with which the array was created. We have seen in the example that this element type is not necessarily the static element type of the array being updated. If the test fails, an ArrayStoreException is raised.

Scala solves this problem instead statically, by disallowing the second line at compile-time, because arrays in Scala have non-variant subtyping. This raises the question how a Scala compiler verifies that variance annotations are correct. If we had simply declared arrays co-variant, how would the potential problem have been detected?

Scala uses a conservative approximation to verify soundness of variance annotations. A covariant type parameter of a class may only appear in co-variant positions inside the class. Among the co-variant positions are the types of values in the class, the result types of methods in the class, and type arguments to other covariant types. Not co-variant are types of formal method parameters. Hence, the following class definition would have been rejected

So far, so good. Intuitively, the compiler was correct in rejecting the update procedure in a co-variant class because update potentially changes state, and therefore undermines the soundness of co-variant subtyping.

However, there are also methods which do not mutate state, but where a type parameter still appears contra-variantly. An example is push in type Stack. Again the Scala compiler will reject the definition of this method for co-variant stacks.

This is a pity, because, unlike arrays, stacks are purely functional data structures and therefore should enable co-variant subtyping. However, there is a a way to solve the problem by using a polymorphic method with a lower type parameter bound.

### 8.3 Lower Bounds

We have seen upper bounds for type parameters. In a type parameter declaration such as T <: U, the type parameter T is restricted to range only over subtypes of type U. Symmetrical to this are lower bounds in Scala. In a type parameter declaration T >: S, the type parameter T is restricted to range only over *supertypes* of type S. (One can also combine lower and upper bounds, as in T >: S <: U.)

Using lower bounds, we can generalize the push method in Stack as follows.

```
class Stack[+A] {
  def push[B >: A](x: B): Stack[B] = new NonEmptyStack(x, this)
```

Technically, this solves our variance problem since now the type parameter A appears no longer as a parameter type of method push. Instead, it appears as lower bound for another type parameter of a method, which is classified as a co-variant position. Hence, the Scala compiler accepts the new definition of push.

In fact, we have not only solved the technical variance problem but also have generalized the definition of push. Before, we were required to push only elements with types that conform to the declared element type of the stack. Now, we can push also elements of a supertype of this type, but the type of the returned stack will change accordingly. For instance, we can now push an AnyRef onto a stack of Strings, but the resulting stack will be a stack of AnyRefs instead of a stack of Strings!

In summary, one should not hesitate to add variance annotations to your data structures, as this yields rich natural subtyping relationships. The compiler will detect potential soundness problems. Even if the compiler's approximation is too conservative, as in the case of method push of class Stack, this will often suggest a useful generalization of the contested method.

## 8.4 Least Types

Scala does not allow one to parameterize objects with types. That's why we originally defined a generic class EmptyStack[A], even though a single value denoting empty stacks of arbitrary type would do. For co-variant stacks, however, one can use the following idiom:

```
object EmptyStack extends Stack[Nothing] { ... }
```

The bottom type Nothing contains no value, so the type Stack[Nothing] expresses the fact that an EmptyStack contains no elements. Furthermore, Nothing is a subtype of all other types. Hence, for co-variant stacks, Stack[Nothing] is a subtype of Stack[T], for any other type T. This makes it possible to use a single empty stack object in user code. For instance:

8.4 Least Types 61

```
val s = EmptyStack.push("abc").push(new AnyRef())
```

Let's analyze the type assignment for this expression in detail. The EmptyStack object is of type Stack[Nothing], which has a method

```
push[B >: Nothing](elem: B): Stack[B] .
```

Local type inference will determine that the type parameter B should be instantiated to String in the application EmptyStack.push("abc"). The result type of that application is hence Stack[String], which in turn has a method

```
push[B >: String](elem: B): Stack[B] .
```

The final part of the value definition above is the application of this method to **new** AnyRef(). Local type inference will determine that the type parameter b should this time be instantiated to AnyRef, with result type Stack[AnyRef]. Hence, the type assigned to value s is Stack[AnyRef].

Besides Nothing, which is a subtype of every other type, there is also the type Null, which is a subtype of scala. AnyRef, and every class derived from it. The **null** literal in Scala is the only value of that type. This makes **null** compatible with every reference type, but not with a value type such as Int.

We conclude this section with the complete improved definition of stacks. Stacks have now co-variant subtyping, the push method has been generalized, and the empty stack is represented by a single object.

```
abstract class Stack[+A] {
  def push[B >: A](x: B): Stack[B] = new NonEmptyStack(x, this)
  def isEmpty: Boolean
  def top: A
  def pop: Stack[A]
}
object EmptyStack extends Stack[Nothing] {
  def isEmpty = true
  def top = error("EmptyStack.top")
  def pop = error("EmptyStack.pop")
}
class NonEmptyStack[+A](elem: A, rest: Stack[A]) extends Stack[A] {
  def isEmpty = false
  def top = elem
  def pop = rest
}
```

Many classes in the Scala library are generic. We now present two commonly used families of generic classes, tuples and functions. The discussion of another common class, lists, is deferred to the next chapter.

## 8.5 Tuples

Sometimes, a function needs to return more than one result. For instance, take the function divmod which returns the integer quotient and rest of two given integer arguments. Of course, one can define a class to hold the two results of divmod, as in:

```
case class TwoInts(first: Int, second: Int)
def divmod(x: Int, y: Int): TwoInts = new TwoInts(x / y, x % y)
```

However, having to define a new class for every possible pair of result types is very tedious. In Scala one can use instead a generic class Tuple2, which is defined as follows:

```
package scala
case class Tuple2[A, B](_1: A, _2: B)
```

With Tuple2, the divmod method can be written as follows.

```
def divmod(x: Int, y: Int) = new Tuple2[Int, Int](x / y, x % y)
```

As usual, type parameters to constructors can be omitted if they are deducible from value arguments. There exist also tuple classes for every other number of elements (the current Scala implementation limits this to tuples of some reasonable number of elements).

How are elements of tuples accessed? Since tuples are case classes, there are two possibilities. One can either access a tuple's fields using the names of the constructor parameters  $_i$ , as in the following example:

```
val xy = divmod(x, y)
println("quotient: " + xy._1 + ", rest: " + xy._2)
```

Or one uses pattern matching on tuples, as in the following example:

```
divmod(x, y) match {
  case Tuple2(n, d) =>
    println("quotient: " + n + ", rest: " + d)
}
```

Note that type parameters are never used in patterns; it would have been illegal to write case Tuple2[Int, Int](n, d).

Tuples are so convenient that Scala defines special syntax for them. To form a tuple with n elements  $x_1, ..., x_n$  one can write  $(x_1, ..., x_n)$ . This is equivalent to Tuple  $n(x_1, ..., x_n)$ . The (...) syntax works equivalently for types and for patterns. With that tuple syntax, the divmod example is written as follows:

```
def divmod(x: Int, y: Int): (Int, Int) = (x / y, x \% y)
```

8.6 Functions 63

```
divmod(x, y) match {
  case (n, d) => println("quotient: " + n + ", rest: " + d)
}
```

## 8.6 Functions

Scala is a functional language in that functions are first-class values. Scala is also an object-oriented language in that every value is an object. It follows that functions are objects in Scala. For instance, a function from type String to type Int is represented as an instance of the trait Function1[String, Int]. The Function1 trait is defined as follows.

```
package scala
trait Function1[-A, +B] {
  def apply(x: A): B
}
```

Besides Function1, there are also definitions of for functions of all other arities (the current implementation implements this only up to a reasonable limit). That is, there is one definition for each possible number of function parameters. Scala's function type syntax  $(T_1, \ldots, T_n) \Rightarrow S$  is simply an abbreviation for the parameterized type Function  $n[T_1, \ldots, T_n, S]$ .

Scala uses the same syntax f(x) for function application, no matter whether f is a method or a function object. This is made possible by the following convention: A function application f(x) where f is an object (as opposed to a method) is taken to be a shorthand for f. apply(x). Hence, the apply method of a function type is inserted automatically where this is necessary.

That's also why we defined array subscripting in Section 8.2 by an apply method. For any array a, the subscript operation a(i) is taken to be a shorthand for a .apply(i).

Functions are an example where a contra-variant type parameter declaration is useful. For example, consider the following code:

```
val f: (AnyRef => Int) = x => x.hashCode()
val g: (String => Int) = f
g("abc")
```

It's sound to bind the value g of type String  $\Rightarrow$  Int to f, which is of type AnyRef  $\Rightarrow$  Int. Indeed, all one can do with function of type String  $\Rightarrow$  Int is pass it a string in order to obtain an integer. Clearly, the same works for function f: If we pass it a string (or any other object), we obtain an integer. This demonstrates that function subtyping is contra-variant in its argument type whereas it is covariant in its result type. In short,  $S \Rightarrow T$  is a subtype of  $S' \Rightarrow T'$ , provided S' is a subtype of  $S' \Rightarrow T'$  and  $S' \Rightarrow T' \Rightarrow T'$  is a subtype of  $S' \Rightarrow T' \Rightarrow T'$ .

### **Example 8.6.1** Consider the Scala code

```
val plus1: (Int \Rightarrow Int) = (x: Int) \Rightarrow x + 1 plus1(2)
```

This is expanded into the following object code.

```
val plus1: Function1[Int, Int] = new Function1[Int, Int] {
  def apply(x: Int): Int = x + 1
}
plus1.apply(2)
```

Here, the object creation **new** Function1[Int, Int]{ ...} represents an instance of an *anonymous class*. It combines the creation of a new Function1 object with an implementation of the apply method (which is abstract in Function1). Equivalently, but more verbosely, one could have used a local class:

```
val plus1: Function1[Int, Int] = {
  class Local extends Function1[Int, Int] {
    def apply(x: Int): Int = x + 1
  }
  new Local: Function1[Int, Int]
}
plus1.apply(2)
```

## Chapter 9

## Lists

Lists are an important data structure in many Scala programs. A list containing the elements  $x_1, ..., x_n$  is written List $(x_1, ..., x_n)$ . Examples are:

```
val fruit = List("apples", "oranges", "pears")
val nums = List(1, 2, 3, 4)
val diag3 = List(List(1, 0, 0), List(0, 1, 0), List(0, 0, 1))
val empty = List()
```

Lists are similar to arrays in languages such as C or Java, but there are also three important differences. First, lists are immutable. That is, elements of a list cannot be changed by assignment. Second, lists have a recursive structure, whereas arrays are flat. Third, lists support a much richer set of operations than arrays usually do.

## 9.1 Using Lists

**The List type.** Like arrays, lists are *homogeneous*. That is, the elements of a list all have the same type. The type of a list with elements of type T is written List[T] (compare to T[] in Java).

```
val fruit: List[String] = List("apples", "oranges", "pears")
val nums : List[Int] = List(1, 2, 3, 4)
val diag3: List[List[Int]] = List(List(1, 0, 0), List(0, 1, 0), List(0, 0, 1))
val empty: List[Int] = List()
```

**List constructors.** All lists are built from two more fundamental constructors, Nil and :: (pronounced "cons"). Nil represents an empty list. The infix operator :: expresses list extension. That is, x:: xs represents a list whose first element is x, which is followed by (the elements of) list xs. Hence, the list values above could al-

66 Lists

so have been defined as follows (in fact their previous definition is simply syntactic sugar for the definitions below).

The '::' operation associates to the right: A :: B :: C is interpreted as A :: (B :: C). Therefore, we can drop the parentheses in the definitions above. For instance, we can write shorter

```
val nums = 1 :: 2 :: 3 :: 4 :: Nil
```

**Basic operations on lists.** All operations on lists can be expressed in terms of the following three:

These operations are defined as methods of list objects. So we invoke them by selecting from the list that's operated on. Examples:

```
empty.isEmpty = true
fruit.isEmpty = false
fruit.head = "apples"
fruit.tail.head = "oranges"
diag3.head = List(1, 0, 0)
```

The head and tail methods are defined only for non-empty lists. When selected from an empty list, they throw an exception.

As an example of how lists can be processed, consider sorting the elements of a list of numbers into ascending order. One simple way to do so is *insertion sort*, which works as follows: To sort a non-empty list with first element x and rest xs, sort the remainder xs and insert the element x at the right position in the result. Sorting an empty list will yield the empty list. Expressed as Scala code:

```
def isort(xs: List[Int]): List[Int] =
  if (xs.isEmpty) Nil
  else insert(xs.head, isort(xs.tail))
```

**Exercise 9.1.1** Provide an implementation of the missing function insert.

**List patterns.** In fact, :: is defined as a case class in Scala's standard library. Hence, it is possible to decompose lists by pattern matching, using patterns composed from the Nil and :: constructors. For instance, isort can be written alternatively as follows.

```
def isort(xs: List[Int]): List[Int] = xs match {
   case List() => List()
   case x :: xs1 => insert(x, isort(xs1))
}
where

def insert(x: Int, xs: List[Int]): List[Int] = xs match {
   case List() => List(x)
   case y :: ys => if (x <= y) x :: xs else y :: insert(x, ys)
}</pre>
```

#### 9.2 Definition of class List I: First Order Methods

Lists are not built in in Scala; they are defined by an abstract class List, which comes with two subclasses for :: and Nil. In the following we present a tour through class List.

```
package scala
abstract class List[+A] {
```

List is an abstract class, so one cannot define elements by calling the empty List constructor (e.g. by new List). The class has a type parameter a. It is co-variant in this parameter, which means that List[S] <: List[T] for all types S and T such that S <: T. The class is situated in the package scala. This is a package containing the most important standard classes of Scala. List defines a number of methods, which are explained in the following.

**Decomposing lists.** First, there are the three basic methods is Empty, head, tail. Their implementation in terms of pattern matching is straightforward:

```
def isEmpty: Boolean = this match {
  case Nil => true
  case x :: xs => false
}
def head: A = this match {
  case Nil => error("Nil.head")
  case x :: xs => x
}
def tail: List[A] = this match {
```

68 Lists

```
case Nil => error("Nil.tail")
case x :: xs => xs
}
```

The next function computes the length of a list.

```
def length: Int = this match {
  case Nil => 0
  case x :: xs => 1 + xs.length
}
```

**Exercise 9.2.1** Design a tail-recursive version of length.

The next two functions are the complements of head and tail.

```
def last: A
def init: List[A]
```

xs.last returns the last element of list xs, whereas xs.init returns all elements of xs except the last. Both functions have to traverse the entire list, and are thus less efficient than their head and tail analogues. Here is the implementation of last.

The implementation of init is analogous.

The next three functions return a prefix of the list, or a suffix, or both.

```
def take(n: Int): List[A] =
   if (n == 0 || isEmpty) Nil else head :: tail.take(n-1)

def drop(n: Int): List[A] =
   if (n == 0 || isEmpty) this else tail.drop(n-1)

def split(n: Int): (List[A], List[A]) = (take(n), drop(n))
```

(xs take n) returns the first n elements of list xs, or the whole list, if its length is smaller than n. (xs drop n) returns all elements of xs except the n first ones. Finally, (xs split n) returns a pair consisting of the lists resulting from xs take n and xs drop n.

The next function returns an element at a given index in a list. It is thus analogous to array subscripting. Indices start at 0.

```
def apply(n: Int): A = drop(n).head
```

The apply method has a special meaning in Scala. An object with an apply method can be applied to arguments as if it was a function. For instance, to pick the 3'rd element of a list xs, one can write either xs.apply(3) or xs(3) – the latter expression expands into the first.

With take and drop, we can extract sublists consisting of consecutive elements of the original list. To extract the sublist  $xs_m, ..., xs_{n-1}$  of a list xs, use:

```
xs.drop(m).take(n - m)
```

**Zipping lists.** The next function combines two lists into a list of pairs. Given two lists

```
xs = List(x_1, ..., x_n), and ys = List(y_1, ..., y_n),
```

xs zip ys constructs the list List( $(x_1, y_1), \ldots, (x_n, y_n)$ ). If the two lists have different lengths, the longer one of the two is truncated. Here is the definition of zip – note that it is a polymorphic method.

```
def zip[B](that: List[B]): List[(a,b)] =
  if (this.isEmpty || that.isEmpty) Nil
  else (this.head, that.head) :: (this.tail zip that.tail)
```

**Consing lists..** Like any infix operator, :: is also implemented as a method of an object. In this case, the object is the list that is extended. This is possible, because operators ending with a ':' character are treated specially in Scala. All such operators are treated as methods of their right operand. E.g.,

```
x :: y = y...(x) whereas x + y = x.+(y)
```

Note, however, that operands of a binary operation are in each case evaluated from left to right. So, if D and E are expressions with possible side-effects, D:: E is translated to  $\{val \ x = D; \ E.::(x)\}$  in order to maintain the left-to-right order of operand evaluation.

Another difference between operators ending in a ':' and other operators concerns their associativity. Operators ending in ':' are right-associative, whereas other operators are left-associative. E.g.,

```
x :: y :: z = x :: (y :: z) whereas x + y + z = (x + y) + z
```

The definition of :: as a method in class List is as follows:

70 Lists

```
def ::[B >: A](x: B): List[B] = new scala.::(x, this)
```

Note that :: is defined for all elements x of type B and lists of type List[A] such that the type B of x is a supertype of the list's element type A. The result is in this case a list of B's. This is expressed by the type parameter B with lower bound A in the signature of ::.

**Concatenating lists.** An operation similar to :: is list concatenation, written ':::'. The result of (xs ::: ys) is a list consisting of all elements of xs, followed by all elements of ys. Because it ends in a colon, ::: is right-associative and is considered as a method of its right-hand operand. Therefore,

```
xs ::: ys ::: zs = xs ::: (ys ::: zs)
= zs.:::(ys).:::(xs)
```

Here is the implementation of the ::: method:

```
def :::[B >: A](prefix: List[B]): List[B] = prefix match {
  case Nil => this
  case p :: ps => this.:::(ps).::(p)
}
```

**Reversing lists.** Another useful operation is list reversal. There is a method reverse in List to that effect. Let's try to give its implementation:

```
def reverse[A](xs: List[A]): List[A] = xs match {
  case Nil => Nil
  case x :: xs => reverse(xs) ::: List(x)
}
```

This implementation has the advantage of being simple, but it is not very efficient. Indeed, one concatenation is executed for every element in the list. List concatenation takes time proportional to the length of its first operand. Therefore, the complexity of reverse(xs) is

```
n + (n-1) + ... + 1 = n(n+1)/2
```

where *n* is the length of xs. Can reverse be implemented more efficiently? We will see later that there exists another implementation which has only linear complexity.

### 9.3 Example: Merge sort

The insertion sort presented earlier in this chapter is simple to formulate, but also not very efficient. It's average complexity is proportional to the square of the length of the input list. We now design a program to sort the elements of a list which is more efficient than insertion sort. A good algorithm for this is *merge sort*, which works as follows.

First, if the list has zero or one elements, it is already sorted, so one returns the list unchanged. Longer lists are split into two sub-lists, each containing about half the elements of the original list. Each sub-list is sorted by a recursive call to the sort function, and the resulting two sorted lists are then combined in a merge operation.

For a general implementation of merge sort, we still have to specify the type of list elements to be sorted, as well as the function to be used for the comparison of elements. We obtain a function of maximal generality by passing these two items as parameters. This leads to the following implementation.

```
def msort[A](less: (A, A) => Boolean)(xs: List[A]): List[A] = {
    def merge(xs1: List[A], xs2: List[A]): List[A] =
        if (xs1.isEmpty) xs2
        else if (xs2.isEmpty) xs1
        else if (less(xs1.head, xs2.head)) xs1.head :: merge(xs1.tail, xs2)
        else xs2.head :: merge(xs1, xs2.tail)
    val n = xs.length/2
    if (n == 0) xs
        else merge(msort(less)(xs take n), msort(less)(xs drop n))
}
```

The complexity of msort is  $O(N \log(N))$ , where N is the length of the input list. To see why, note that splitting a list in two and merging two sorted lists each take time proportional to the length of the argument list(s). Each recursive call of msort halves the number of elements in its input, so there are  $O(\log(N))$  consecutive recursive calls until the base case of lists of length 1 is reached. However, for longer lists each call spawns off two further calls. Adding everything up we obtain that at each of the  $O(\log(N))$  call levels, every element of the original lists takes part in one split operation and in one merge operation. Hence, every call level has a total cost proportional to O(N). Since there are  $O(\log(N))$  call levels, we obtain an overall cost of  $O(N \log(N))$ . That cost does not depend on the initial distribution of elements in the list, so the worst case cost is the same as the average case cost. This makes merge sort an attractive algorithm for sorting lists.

Here is an example how msort is used.

```
msort((x: Int, y: Int) \Rightarrow x < y)(List(5, 7, 1, 3))
```

The definition of msort is curried, to make it easy to specialize it with particular comparison functions. For instance,

```
val intSort = msort((x: Int, y: Int) => x < y)
val reverseSort = msort((x: Int, y: Int) => x > y)
```

72 Lists

#### 9.4 Definition of class List II: Higher-Order Methods

The examples encountered so far show that functions over lists often have similar structures. We can identify several patterns of computation over lists, like:

- transforming every element of a list in some way.
- extracting from a list all elements satisfying a criterion.
- combine the elements of a list using some operator.

Functional programming languages enable programmers to write general functions which implement patterns like this by means of higher order functions. We now discuss a set of commonly used higher-order functions, which are implemented as methods in class List.

**Mapping over lists.** A common operation is to transform each element of a list and then return the lists of results. For instance, to scale each element of a list by a given factor.

```
def scaleList(xs: List[Double], factor: Double): List[Double] = xs match {
   case Nil => xs
   case x :: xs1 => x * factor :: scaleList(xs1, factor)
}
```

This pattern can be generalized to the map method of class List:

```
abstract class List[A] { ...
  def map[B](f: A => B): List[B] = this match {
    case Nil => this
    case x :: xs => f(x) :: xs.map(f)
  }
```

Using map, scaleList can be more concisely written as follows.

```
def scaleList(xs: List[Double], factor: Double) =
    xs map (x => x * factor)
```

As another example, consider the problem of returning a given column of a matrix which is represented as a list of rows, where each row is again a list. This is done by the following function column.

```
def column[A](xs: List[List[A]], index: Int): List[A] =
    xs map (row => row(index))
```

Closely related to map is the foreach method, which applies a given function to all elements of a list, but does not construct a list of results. The function is thus applied only for its side effect. foreach is defined as follows.

```
def foreach(f: A => Unit) {
    this match {
       case Nil => ()
       case x :: xs => f(x); xs.foreach(f)
    }
}
```

This function can be used for printing all elements of a list, for instance:

```
xs foreach (x \Rightarrow println(x))
```

**Exercise 9.4.1** Consider a function which squares all elements of a list and returns a list with the results. Complete the following two equivalent definitions of squareList.

```
def squareList(xs: List[Int]): List[Int] = xs match {
  case List() => ??
  case y :: ys => ??
}
def squareList(xs: List[Int]): List[Int] =
  xs map ??
```

**Filtering Lists.** Another common operation selects from a list all elements fulfilling a given criterion. For instance, to return a list of all positive elements in some given lists of integers:

```
def posElems(xs: List[Int]): List[Int] = xs match {
  case Nil => xs
  case x :: xs1 => if (x > 0) x :: posElems(xs1) else posElems(xs1)
}
```

This pattern is generalized to the filter method of class List:

```
def filter(p: A => Boolean): List[A] = this match {
  case Nil => this
  case x :: xs => if (p(x)) x :: xs.filter(p) else xs.filter(p)
}
```

Using filter, posElems can be more concisely written as follows.

```
def posElems(xs: List[Int]): List[Int] =
    xs filter (x => x > 0)
```

An operation related to filtering is testing whether all elements of a list satisfy a certain condition. Dually, one might also be interested in the question whether there

74 Lists

exists an element in a list that satisfies a certain condition. These operations are embodied in the higher-order functions for all and exists of class List.

```
def forall(p: A => Boolean): Boolean =
  isEmpty || (p(head) && (tail forall p))
def exists(p: A => Boolean): Boolean =
  !isEmpty && (p(head) || (tail exists p))
```

To illustrate the use of foral1, consider the question of whether a number if prime. Remember that a number n is prime of it can be divided without remainder only by one and itself. The most direct translation of this definition would test that n divided by all numbers from 2 up to and excluding itself gives a non-zero remainder. This list of numbers can be generated using a function List.range which is defined in object List as follows.

```
package scala
object List { ...
  def range(from: Int, end: Int): List[Int] =
    if (from >= end) Nil else from :: range(from + 1, end)
```

For example, List.range(2, n) generates the list of all integers from 2 up to and excluding n. The function is Prime can now simply be defined as follows.

```
def isPrime(n: Int) =
  List.range(2, n) forall (x => n % x != 0)
```

We see that the mathematical definition of prime-ness has been translated directly into Scala code.

Exercise: Define for all and exists in terms of filter.

**Folding and Reducing Lists.** Another common operation is to combine the elements of a list with some operator. For instance:

```
sum(List(x_1, ..., x_n)) = 0 + x_1 + ... + x_n

product(List(x_1, ..., x_n)) = 1 * x_1 * ... * x_n
```

Of course, we can implement both functions with a recursive scheme:

```
def sum(xs: List[Int]): Int = xs match {
   case Nil => 0
   case y :: ys => y + sum(ys)
}
def product(xs: List[Int]): Int = xs match {
   case Nil => 1
   case y :: ys => y * product(ys)
}
```

But we can also use the generalization of this program scheme embodied in the reduceLeft method of class List. This method inserts a given binary operator between adjacent elements of a given list. E.g.

```
List(x_1, \ldots, x_n).reduceLeft(op) = (\ldots(x_1 \text{ op } x_2) \text{ op } \ldots) op x_n
```

Using reduceLeft, we can make the common pattern in sum and product apparent:

```
def sum(xs: List[Int]) = (0 :: xs) reduceLeft \{(x, y) \Rightarrow x + y\}
def product(xs: List[Int]) = (1 :: xs) reduceLeft \{(x, y) \Rightarrow x * y\}
```

Here is the implementation of reduceLeft.

```
def reduceLeft(op: (A, A) => A): A = this match {
   case Nil => error("Nil.reduceLeft")
   case x :: xs => (xs foldLeft x)(op)
}
def foldLeft[B](z: B)(op: (B, A) => B): B = this match {
   case Nil => z
   case x :: xs => (xs foldLeft op(z, x))(op)
}
```

We see that the reduceLeft method is defined in terms of another generally useful method, foldLeft. The latter takes as additional parameter an *accumulator* z, which is returned when foldLeft is applied on an empty list. That is,

```
(List(x_1, \ldots, x_n) \text{ foldLeft z})(op) = (\ldots(z \text{ op } x_1) \text{ op } \ldots) \text{ op } x_n
```

The sum and product methods can be defined alternatively using foldLeft:

```
def sum(xs: List[Int]) = (xs foldLeft 0) {(x, y) => x + y}
def product(xs: List[Int]) = (xs foldLeft 1) {(x, y) => x * y}
```

**FoldRight and ReduceRight.** Applications of foldLeft and reduceLeft expand to left-leaning trees. They have duals foldRight and reduceRight, which produce right-leaning trees.

```
List(x_1, \ldots, x_n).reduceRight(op) = x_1 op ( \ldots (x_{n-1} op x_n) \ldots)
(List(x_1, \ldots, x_n) foldRight acc)(op) = x_1 op ( \ldots (x_n op acc) \ldots)
```

These are defined as follows.

```
def reduceRight(op: (A, A) => A): A = this match {
  case Nil => error("Nil.reduceRight")
  case x :: Nil => x
  case x :: xs => op(x, xs.reduceRight(op))
```

76 Lists

```
}
def foldRight[B](z: B)(op: (A, B) => B): B = this match {
  case Nil => z
  case x :: xs => op(x, (xs foldRight z)(op))
}
```

Class List defines also two symbolic abbreviations for foldLeft and foldRight:

```
def /:[B](z: B)(f: (B, A) \Rightarrow B): B = foldLeft(z)(f)
def :\setminus[B](z: B)(f: (A, B) \Rightarrow B): B = foldRight(z)(f)
```

The method names picture the left/right leaning trees of the fold operations by forward or backward slashes. The : points in each case to the list argument whereas the end of the slash points to the accumulator (or: zero) argument z. That is,

```
(z /: List(x_1, ..., x_n))(op) = (...(z op x_1) op ...) op x_n
(List(x_1, ..., x_n) :\setminus z)(op) = x_1 op (...(x_n op z)...)
```

For associative and commutative operators, /: and :\ are equivalent (even though there may be a difference in efficiency).

**Exercise 9.4.2** Consider the problem of writing a function flatten, which takes a list of element lists as arguments. The result of flatten should be the concatenation of all element lists into a single list. Here is an implementation of this method in terms of :\.

```
def flatten[A](xs: List[List[A]]): List[A] =
  (xs :\ (Nil: List[A])) {(x, xs) => x ::: xs}
```

Consider replacing the body of flatten by

```
((Nil: List[A]) /: xs) ((xs, x) => xs ::: x)
```

What would be the difference in asymptotic complexity between the two versions of flatten?

In fact flatten is predefined together with a set of other userful function in an object called List in the standard Scala library. It can be accessed from user program by calling List.flatten. Note that flatten is not a method of class List – it would not make sense there, since it applies only to lists of lists, not to all lists in general.

**List Reversal Again.** We have seen in Section 9.2 an implementation of method reverse whose run-time was quadratic in the length of the list to be reversed. We now develop a new implementation of reverse, which has linear cost. The idea is to use a foldLeft operation based on the following program scheme.

```
class List[+A] { ...
```

```
def reverse: List[A] = (z? /: this)(op?)
```

It only remains to fill in the z? and op? parts. Let's try to deduce them from examples.

Hence, z? must be Nil. To deduce the second operand, let's study reversal of a list of length one.

Hence, op(Nil, x) equals List(x), which is the same as x :: Nil. This suggests to take as op the :: operator with its operands exchanged. Hence, we arrive at the following implementation for reverse, which has linear complexity.

```
def reverse: List[A] =
  ((Nil: List[A]) /: this) {(xs, x) => x :: xs}
```

(Remark: The type annotation of Nil is necessary to make the type inferencer work.)

**Exercise 9.4.3** Fill in the missing expressions to complete the following definitions of some basic list-manipulation operations as fold operations.

```
def mapFun[A, B](xs: List[A], f: A => B): List[B] =
  (xs :\ List[B]()){ ?? }

def lengthFun[A](xs: List[A]): int =
  (0 /: xs){ ?? }
```

**Nested Mappings.** We can employ higher-order list processing functions to express many computations that are normally expressed as nested loops in imperative languages.

As an example, consider the following problem: Given a positive integer n, find all pairs of positive integers i and j, where  $1 \le j < i < n$  such that i + j is prime. For

78 Lists

instance, if n = 7, the pairs are

A natural way to solve this problem consists of two steps. In a first step, one generates the sequence of all pairs (i, j) of integers such that  $1 \le j < i < n$ . In a second step one then filters from this sequence all pairs (i, j) such that i + j is prime.

Looking at the first step in more detail, a natural way to generate the sequence of pairs consists of three sub-steps. First, generate all integers between 1 and n for i.

Second, for each integer i between 1 and n, generate the list of pairs (i,1) up to (i,i-1). This can be achieved by a combination of range and map:

```
List.range(1, i) map (x \Rightarrow (i, x))
```

Finally, combine all sublists using foldRight with :::. Putting everything together gives the following expression:

```
List.range(1, n)
  .map(i => List.range(1, i).map(x => (i, x)))
  .foldRight(List[(Int, Int)]()) {(xs, ys) => xs ::: ys}
  .filter(pair => isPrime(pair._1 + pair._2))
```

**Flattening Maps.** The combination of mapping and then concatenating sublists resulting from the map is so common that we there is a special method for it in class List:

```
abstract class List[+A] { ...
  def flatMap[B](f: A => List[B]): List[B] = this match {
    case Nil => Nil
    case x :: xs => f(x) ::: (xs flatMap f)
  }
}
```

With flatMap, the pairs-whose-sum-is-prime expression could have been written more concisely as follows.

```
List.range(1, n)
  .flatMap(i => List.range(1, i).map(x => (i, x)))
  .filter(pair => isPrime(pair._1 + pair._2))
```

9.5 Summary 79

#### 9.5 Summary

This chapter has introduced lists as a fundamental data structure in programming. Since lists are immutable, they are a common data type in functional programming languages. They have a role comparable to arrays in imperative languages. However, the access patterns between arrays and lists are quite different. Where array accessing is always done by indexing, this is much less common for lists. We have seen that scala. List defines a method called apply for indexing however this operation is much more costly than in the case of arrays (linear as opposed to constant time). Instead of indexing, lists are usually traversed recursively, where recursion steps are usually based on a pattern match over the traversed list. There is also a rich set of higher-order combinators which allow one to instantiate a set of predefined patterns of computations over lists.

## Chapter 10

# **For-Comprehensions**

The last chapter demonstrated that higher-order functions such as map, flatMap, filter provide powerful constructions for dealing with lists. But sometimes the level of abstraction required by these functions makes a program hard to understand.

To help understandability, Scala has a special notation which simplifies common patterns of applications of higher-order functions. This notation builds a bridge between set-comprehensions in mathematics and for-loops in imperative languages such as C or Java. It also closely resembles the query notation of relational databases.

As a first example, say we are given a list persons of persons with name and age fields. To print the names of all persons in the sequence which are aged over 20, one can write:

```
for (p <- persons if p.age > 20) yield p.name
```

This is equivalent to the following expression, which uses higher-order functions filter and map:

```
persons filter (p \Rightarrow p.age > 20) map (p \Rightarrow p.name)
```

The for-comprehension looks a bit like a for-loop in imperative languages, except that it constructs a list of the results of all iterations.

Generally, a for-comprehension is of the form

```
for (s) yield e
```

Here, s is a sequence of *generators*, *definitions* and *filters*. A *generator* is of the form val x < -e, where e is a list-valued expression. It binds x to successive values in the list. A *definition* is of the form val x = e. It introduces x as a name for the value of e in the rest of the comprehension. A *filter* is an expression e of type Boolean. It omits from consideration all bindings for which e is **false**. The sequence e starts in each

case with a generator. If there are several generators in a sequence, later generators vary more rapidly than earlier ones.

The sequence *s* may also be enclosed in braces instead of parentheses, in which case the semicolons between generators, definitions and filters can be omitted.

Here are two examples that show how for-comprehensions are used. First, let's redo an example of the previous chapter: Given a positive integer n, find all pairs of positive integers i and j, where  $1 \le j < i < n$  such that i + j is prime. With a for-comprehension this problem is solved as follows:

This is arguably much clearer than the solution using map, flatMap and filter that we have developed previously.

As a second example, consider computing the scalar product of two vectors xs and ys. Using a for-comprehension, this can be written as follows.

```
sum(for ((x, y) \leftarrow xs zip ys) yield x * y)
```

#### 10.1 The N-Queens Problem

For-comprehensions are especially useful for solving combinatorial puzzles. An example of such a puzzle is the 8-queens problem: Given a standard chess-board, place 8 queens such that no queen is in check from any other (a queen can check another piece if they are on the same column, row, or diagonal). We will now develop a solution to this problem, generalizing it to chess-boards of arbitrary size. Hence, the problem is to place n queens on a chess-board of size  $n \times n$ .

To solve this problem, note that we need to place a queen in each row. So we could place queens in successive rows, each time checking that a newly placed queen is not in check from any other queens that have already been placed. In the course of this search, it might arrive that a queen to be placed in row k would be in check in all fields of that row from queens in row 1 to k-1. In that case, we need to abort that part of the search in order to continue with a different configuration of queens in columns 1 to k-1.

This suggests a recursive algorithm. Assume that we have already generated all solutions of placing k-1 queens on a board of size  $n \times n$ . We can represent each such solution by a list of length k-1 of column numbers (which can range from 1 to n). We treat these partial solution lists as stacks, where the column number of the queen in row k-1 comes first in the list, followed by the column number of the queen in row k-2, etc. The bottom of the stack is the column number of the queen placed in the first row of the board. All solutions together are then represented as a

list of lists, with one element for each solution.

Now, to place the k'the queen, we generate all possible extensions of each previous solution by one more queen. This yields another list of solution lists, this time of length k. We continue the process until we have reached solutions of the size of the chess-board n. This algorithmic idea is embodied in function placeQueens below:

#### **Exercise 10.1.1** Write the function

```
def isSafe(col: Int, queens: List[Int], delta: Int): Boolean
```

which tests whether a queen in the given column col is safe with respect to the queens already placed. Here, delta is the difference between the row of the queen to be placed and the row of the first queen in the list.

### 10.2 Querying with For-Comprehensions

The for-notation is essentially equivalent to common operations of database query languages. For instance, say we are given a database books, represented as a list of books, where Book is defined as follows.

```
case class Book(title: String, authors: List[String])
```

Here is a small example database:

```
val books: List[Book] = List(
    Book("Structure and Interpretation of Computer Programs",
        List("Abelson, Harold", "Sussman, Gerald J.")),
    Book("Principles of Compiler Design",
        List("Aho, Alfred", "Ullman, Jeffrey")),
    Book("Programming in Modula-2",
        List("Wirth, Niklaus")),
    Book("Introduction to Functional Programming"),
        List("Bird, Richard")),
    Book("The Java Language Specification",
        List("Gosling, James", "Joy, Bill", "Steele, Guy", "Bracha, Gilad")))
```

Then, to find the titles of all books whose author's last name is "Ullman":

```
for (b <- books; a <- b.authors if a startsWith "Ullman")
yield b.title</pre>
```

(Here, startsWith is a method in java.lang.String). Or, to find the titles of all books that have the string "Program" in their title:

```
for (b <- books if (b.title indexOf "Program") >= 0)
yield b.title
```

Or, to find the names of all authors that have written at least two books in the database.

The last solution is not yet perfect, because authors will appear several times in the list of results. We still need to remove duplicate authors from result lists. This can be achieved with the following function.

```
def removeDuplicates[A](xs: List[A]): List[A] =
  if (xs.isEmpty) xs
  else xs.head :: removeDuplicates(xs.tail filter (x => x != xs.head))
```

Note that the last expression in method removeDuplicates can be equivalently expressed using a for-comprehension.

```
xs.head :: removeDuplicates(for (x <- xs.tail if x != xs.head) yield x)
```

### 10.3 Translation of For-Comprehensions

Every for-comprehension can be expressed in terms of the three higher-order functions map, flatMap and filter. Here is the translation scheme, which is also used by the Scala compiler.

• A simple for-comprehension

```
for (x <- e) yield e'
is translated to
  e.map(x => e')
```

A for-comprehension

```
for (x <- e if f; s) yield e'</pre>
```

where f is a filter and s is a (possibly empty) sequence of generators or filters is translated to

```
for (x \leftarrow e.filter(x \Rightarrow f); s) yield e'
```

and then translation continues with the latter expression.

A for-comprehension

```
for (x <- e; y <- e'; s) yield e''
```

where s is a (possibly empty) sequence of generators or filters is translated to

```
e.flatMap(x => for (y <- e'; s) yield e'')</pre>
```

and then translation continues with the latter expression.

For instance, taking our "pairs of integers whose sum is prime.example:

Here is what we get when we translate this expression:

```
range(1, n)
  .flatMap(i =>
    range(1, i)
        .filter(j => isPrime(i+j))
        .map(j => (i, j)))
```

Conversely, it would also be possible to express functions map, flatMap and filter using for-comprehensions. Here are the three functions again, this time implemented using for-comprehensions.

```
object Demo {
  def map[A, B](xs: List[A], f: A => B): List[B] =
    for (x <- xs) yield f(x)

  def flatMap[A, B](xs: List[A], f: A => List[B]): List[B] =
    for (x <- xs; y <- f(x)) yield y

  def filter[A](xs: List[A], p: A => Boolean): List[A] =
    for (x <- xs if p(x)) yield x
}</pre>
```

Not surprisingly, the translation of the for-comprehension in the body of Demo.map will produce a call to map in class List. Similarly, Demo.flatMap and Demo.filter translate to flatMap and filter in class List.

**Exercise 10.3.1** Define the following function in terms of **for**.

```
def flatten[A](xss: List[List[A]]): List[A] =
  (xss :\ (Nil: List[A])) ((xs, ys) => xs ::: ys)
```

#### Exercise 10.3.2 Translate

```
for (b <- books; a <- b.authors if a startsWith "Bird") yield b.title
for (b <- books if (b.title indexOf "Program") >= 0) yield b.title
```

to higher-order functions.

#### 10.4 For-Loops

For-comprehensions resemble for-loops in imperative languages, except that they produce a list of results. Sometimes, a list of results is not needed but we would still like the flexibility of generators and filters in iterations over lists. This is made possible by a variant of the for-comprehension syntax, which expresses for-loops:

```
for ( s ) e
```

This construct is the same as the standard for-comprehension syntax except that the keyword **yield** is missing. The for-loop is executed by executing the expression *e* for each element generated from the sequence of generators and filters *s*.

As an example, the following expression prints out all elements of a matrix represented as a list of lists:

```
for (xs <- xss) {
  for (x <- xs) print(x + "\t")
  println()
}</pre>
```

The translation of for-loops to higher-order methods of class List is similar to the translation of for-comprehensions, but is simpler. Where for-comprehensions translate to map and flatMap, for-loops translate in each case to foreach.

### 10.5 Generalizing For

We have seen that the translation of for-comprehensions only relies on the presence of methods map, flatMap, and filter. Therefore it is possible to apply the same

notation to generators that produce objects other than lists; these objects only have to support the three key functions map, flatMap, and filter.

The standard Scala library has several other abstractions that support these three methods and with them support for-comprehensions. We will encounter some of them in the following chapters. As a programmer you can also use this principle to enable for-comprehensions for types you define – these types just need to support methods map, flatMap, and filter.

There are many examples where this is useful: Examples are database interfaces, XML trees, or optional values.

One caveat: It is not assured automatically that the result translating a forcomprehension is well-typed. To ensure this, the types of map, flatMap and filter have to be essentially similar to the types of these methods in class List.

To make this precise, assume you have a parameterized class C[A] for which you want to enable for-comprehensions. Then C should define map, flatMap and filter with the following types:

```
def map[B](f: A => B): C[B]
def flatMap[B](f: A => C[B]): C[B]
def filter(p: A => Boolean): C[A]
```

It would be attractive to enforce these types statically in the Scala compiler, for instance by requiring that any type supporting for-comprehensions implements a standard trait with these methods <sup>1</sup>. The problem is that such a standard trait would have to abstract over the identity of the class C, for instance by taking C as a type parameter. Note that this parameter would be a type constructor, which gets applied to *several different* types in the signatures of methods map and flatMap. Unfortunately, the Scala type system is too weak to express this construct, since it can handle only type parameters which are fully applied types.

<sup>&</sup>lt;sup>1</sup>In the programming language Haskell, which has similar constructs, this abstraction is called a "monad with zero"

## Chapter 11

## **Mutable State**

Most programs we have presented so far did not have side-effects  $^1$ . Therefore, the notion of *time* did not matter. For a program that terminates, any sequence of actions would have led to the same result! This is also reflected by the substitution model of computation, where a rewrite step can be applied anywhere in a term, and all rewritings that terminate lead to the same solution. In fact, this *confluence* property is a deep result in  $\lambda$ -calculus, the theory underlying functional programming.

In this chapter, we introduce functions with side effects and study their behavior. We will see that as a consequence we have to fundamentally modify up the substitution model of computation which we employed so far.

### 11.1 Stateful Objects

We normally view the world as a set of objects, some of which have state that *changes* over time. Normally, state is associated with a set of variables that can be changed in the course of a computation. There is also a more abstract notion of state, which does not refer to particular constructs of a programming language: An object *has state* (or: *is stateful*) if its behavior is influenced by its history.

For instance, a bank account object has state, because the question "can I withdraw 100 CHF?" might have different answers during the lifetime of the account.

In Scala, all mutable state is ultimately built from variables. A variable definition is written like a value definition, but starts with var instead of val. For instance, the following two definitions introduce and initialize two variables x and count.

```
var x: String = "abc"
var count = 111
```

<sup>&</sup>lt;sup>1</sup>We ignore here the fact that some of our program printed to standard output, which technically is a side effect.

90 Mutable State

Like a value definition, a variable definition associates a name with a value. But in the case of a variable definition, this association may be changed later by an assignment. Such assignments are written as in C or Java. Examples:

```
x = "hello"
count = count + 1
```

In Scala, every defined variable has to be initialized at the point of its definition. For instance, the statement **var** x: Int; is *not* regarded as a variable definition, because the initializer is missing<sup>2</sup>. If one does not know, or does not care about, the appropriate initializer, one can use a wildcard instead. I.e.

```
val x: T = _
```

will initialize x to some default value (**null** for reference types, **false** for booleans, and the appropriate version of 0 for numeric value types).

Real-world objects with state are represented in Scala by objects that have variables as members. For instance, here is a class that represents bank accounts.

```
class BankAccount {
  private var balance = 0
  def deposit(amount: Int) {
    if (amount > 0) balance += amount
  }

  def withdraw(amount: Int): Int =
    if (0 < amount && amount <= balance) {
      balance -= amount
      balance
    } else error("insufficient funds")
}</pre>
```

The class defines a variable balance which contains the current balance of an account. Methods deposit and withdraw change the value of this variable through assignments. Note that balance is **private** in class BankAccount – hence it can not be accessed directly outside the class.

To create bank-accounts, we use the usual object creation notation:

```
val myAccount = new BankAccount
```

**Example 11.1.1** Here is a scalaint session that deals with bank accounts.

```
scala> :1 bankaccount.scala
```

<sup>&</sup>lt;sup>2</sup>If a statement like this appears in a class, it is instead regarded as a variable declaration, which introduces abstract access methods for the variable, but does not associate these methods with a piece of state.

```
Loading bankaccount.scala...
defined class BankAccount
scala> val account = new BankAccount
account: BankAccount = BankAccount$class@1797795
scala> account deposit 50
unnamed0: Unit = ()
scala> account withdraw 20
unnamed1: Int = 30
scala> account withdraw 20
unnamed2: Int = 10
scala> account withdraw 15
java.lang.Error: insufficient funds
        at scala.Predef$error(Predef.scala:74)
        at BankAccount$class.withdraw(<console>:14)
        at <init>(<console>:5)
scala>
```

The example shows that applying the same operation (withdraw 20) twice to an account yields different results. So, clearly, accounts are stateful objects.

**Sameness and Change.** Assignments pose new problems in deciding when two expressions are "the same". If assignments are excluded, and one writes

```
val x = E; val y = E
```

where E is some arbitrary expression, then x and y can reasonably be assumed to be the same. I.e. one could have equivalently written

```
val x = E; val y = x
```

(This property is usually called *referential transparency*). But once we admit assignments, the two definition sequences are different. Consider:

```
val x = new BankAccount; val y = new BankAccount
```

To answer the question whether x and y are the same, we need to be more precise what "sameness" means. This meaning is captured in the notion of *operational equivalence*, which, somewhat informally, is stated as follows.

Suppose we have two definitions of x and y. To test whether x and y define the same value, proceed as follows.

- Execute the definitions followed by an arbitrary sequence S of operations that involve x and y. Observe the results (if any).
- Then, execute the definitions with another sequence S' which results from S by renaming all occurrences of y in S to x.

92 Mutable State

- If the results of running S' are different, then surely x and y are different.
- On the other hand, if all possible pairs of sequences {S, S'} yield the same results, then x and y are the same.

In other words, operational equivalence regards two definitions x and y as defining the same value, if no possible experiment can distinguish between x and y. An experiment in this context are two version of an arbitrary program which use either x or y.

Given this definition, let's test whether

```
val x = new BankAccount; val y = new BankAccount
```

defines values x and y which are the same. Here are the definitions again, followed by a test sequence:

```
> val x = new BankAccount
> val y = new BankAccount
> x deposit 30
30
> y withdraw 20
java.lang.RuntimeException: insufficient funds
```

Now, rename all occurrences of y in that sequence to x. We get:

```
> val x = new BankAccount
> val y = new BankAccount
> x deposit 30
30
> x withdraw 20
10
```

Since the final results are different, we have established that x and y are not the same. On the other hand, if we define

```
val x = new BankAccount; val y = x
```

then no sequence of operations can distinguish between x and y, so x and y are the same in this case.

**Assignment and the Substitution Model.** These examples show that our previous substitution model of computation cannot be used anymore. After all, under this model we could always replace a value name by its defining expression. For instance in

```
val x = new BankAccount; val y = x
```

the x in the definition of y could be replaced by new BankAccount. But we have seen that this change leads to a different program. So the substitution model must be invalid, once we add assignments.

#### 11.2 Imperative Control Structures

Scala has the **while** and **do-while** loop constructs known from the C and Java languages. There is also a single branch **if** which leaves out the else-part as well as a **return** statement which aborts a function prematurely. This makes it possible to program in a conventional imperative style. For instance, the following function, which computes the n'th power of a given parameter x, is implemented using **while** and single-branch **if**.

```
def power(x: Double, n: Int): Double = {
  var r = 1.0
  var i = n
  var j = 0
  while (j < 32) {
    r = r * r
    if (i < 0)
        r *= x
        i = i << 1
        j += 1
    }
  r</pre>
```

These imperative control constructs are in the language for convenience. They could have been left out, as the same constructs can be implemented using just functions. As an example, let's develop a functional implementation of the while loop. whileLoop should be a function that takes two parameters: a condition, of type Boolean, and a command, of type Unit. Both condition and command need to be passed by-name, so that they are evaluated repeatedly for each loop iteration. This leads to the following definition of whileLoop.

```
def whileLoop(condition: => Boolean)(command: => Unit) {
   if (condition) {
      command; whileLoop(condition)(command)
    } else ()
}
```

Note that whileLoop is tail recursive, so it operates in constant stack space.

**Exercise 11.2.1** Write a function repeatLoop, which should be applied as follows:

94 Mutable State

```
repeatLoop { command } ( condition )
```

Is there also a way to obtain a loop syntax like the following?

```
repeatLoop { command } until ( condition )
```

Some other control constructs known from C and Java are missing in Scala: There are no break and continue jumps for loops. There are also no for-loops in the Java sense – these have been replaced by the more general for-loop construct discussed in Section 10.4.

#### 11.3 Extended Example: Discrete Event Simulation

We now discuss an example that demonstrates how assignments and higher-order functions can be combined in interesting ways. We will build a simulator for digital circuits.

The example is taken from Abelson and Sussman's book [?]. We augment their basic (Scheme-) code by an object-oriented structure which allows code-reuse through inheritance. The example also shows how discrete event simulation programs in general are structured and built.

We start with a little language to describe digital circuits. A digital circuit is built from *wires* and *function boxes*. Wires carry signals which are transformed by function boxes. We will represent signals by the booleans **true** and **false**.

Basic function boxes (or: gates) are:

- An *inverter*, which negates its signal
- An *and-gate*, which sets its output to the conjunction of its input.
- An *or-gate*, which sets its output to the disjunction of its input.

Other function boxes can be built by combining basic ones.

Gates have *delays*, so an output of a gate will change only some time after its inputs change.

**A Language for Digital Circuits.** We describe the elements of a digital circuit by the following set of Scala classes and functions.

First, there is a class Wire for wires. We can construct wires as follows.

```
val a = new Wire
val b = new Wire
val c = new Wire
```

Second, there are procedures

```
def inverter(input: Wire, output: Wire)
def andGate(a1: Wire, a2: Wire, output: Wire)
def orGate(o1: Wire, o2: Wire, output: Wire)
```

which "make" the basic gates we need (as side-effects). More complicated function boxes can now be built from these. For instance, to construct a half-adder, we can define:

```
def halfAdder(a: Wire, b: Wire, s: Wire, c: Wire) {
  val d = new Wire
  val e = new Wire
  orGate(a, b, d)
  andGate(a, b, c)
  inverter(c, e)
  andGate(d, e, s)
}
```

This abstraction can itself be used, for instance in defining a full adder:

```
def fullAdder(a: Wire, b: Wire, cin: Wire, sum: Wire, cout: Wire) {
  val s = new Wire
  val c1 = new Wire
  val c2 = new Wire
  halfAdder(a, cin, s, c1)
  halfAdder(b, s, sum, c2)
  orGate(c1, c2, cout)
}
```

Class Wire and functions inverter, and Gate, and or Gate represent thus a little language in which users can define digital circuits. We now give implementations of this class and these functions, which allow one to simulate circuits. These implementations are based on a simple and general API for discrete event simulation.

**The Simulation API.** Discrete event simulation performs user-defined *actions* at specified *times*. An *action* is represented as a function which takes no parameters and returns a Unit result:

```
type Action = () => Unit
```

The *time* is simulated; it is not the actual "wall-clock" time.

A concrete simulation will be done inside an object which inherits from the abstract Simulation class. This class has the following signature:

```
abstract class Simulation {
```

96 Mutable State

```
def currentTime: Int
  def afterDelay(delay: Int, action: => Action)
  def run()
}
```

Here, currentTime returns the current simulated time as an integer number, afterDelay schedules an action to be performed at a specified delay after currentTime, and run runs the simulation until there are no further actions to be performed.

**The Wire Class.** A wire needs to support three basic actions.

```
getSignal: Boolean returns the current signal on the wire.
setSignal(sig: Boolean) sets the wire's signal to sig.
addAction(p: Action) attaches the specified procedure p to the actions of the wire. All attached action procedures will be executed every time the signal of a wire changes.
```

Here is an implementation of the Wire class:

```
class Wire {
  private var sigVal = false
  private var actions: List[Action] = List()
  def getSignal = sigVal
  def setSignal(s: Boolean) =
    if (s != sigVal) {
      sigVal = s
      actions.foreach(action => action())
    }
  def addAction(a: Action) {
    actions = a :: actions; a()
  }
}
```

Two private variables make up the state of a wire. The variable sigVal represents the current signal, and the variable actions represents the action procedures currently attached to the wire.

**The Inverter Class.** We implement an inverter by installing an action on its input wire, namely the action which puts the negated input signal onto the output signal. The action needs to take effect at InverterDelay simulated time units after the input changes. This suggests the following implementation:

```
def inverter(input: Wire, output: Wire) {
```

```
def invertAction() {
    val inputSig = input.getSignal
    afterDelay(InverterDelay) { output setSignal !inputSig }
}
input addAction invertAction
}
```

**The And-Gate Class.** And-gates are implemented analogously to inverters. The action of an andGate is to output the conjunction of its input signals. This should happen at AndGateDelay simulated time units after any one of its two inputs changes. Hence, the following implementation:

```
def andGate(a1: Wire, a2: Wire, output: Wire) {
    def andAction() {
       val a1Sig = a1.getSignal
       val a2Sig = a2.getSignal
       afterDelay(AndGateDelay) { output setSignal (a1Sig & a2Sig) }
    }
    a1 addAction andAction
    a2 addAction andAction
}
```

**Exercise 11.3.1** Write the implementation of orGate.

**Exercise 11.3.2** Another way is to define an or-gate by a combination of inverters and and gates. Define a function orGate in terms of andGate and inverter. What is the delay time of this function?

**The Simulation Class.** Now, we just need to implement class Simulation, and we are done. The idea is that we maintain inside a Simulation object an *agenda* of actions to perform. The agenda is represented as a list of pairs of actions and the times they need to be run. The agenda list is sorted, so that earlier actions come before later ones.

```
abstract class Simulation {
  case class WorkItem(time: Int, action: Action)
  private type Agenda = List[WorkItem]
  private var agenda: Agenda = List()
```

There is also a private variable curtime to keep track of the current simulated time.

```
private var curtime = 0
```

98 Mutable State

An application of the method afterDelay(delay, block) inserts the element WorkItem(currentTime + delay, () => block) into the agenda list at the appropriate place.

```
private def insert(ag: Agenda, item: WorkItem): Agenda =
   if (ag.isEmpty || item.time < ag.head.time) item :: ag
   else ag.head :: insert(ag.tail, item)

def afterDelay(delay: Int)(block: => Unit) {
   val item = WorkItem(currentTime + delay, () => block)
   agenda = insert(agenda, item)
}
```

An application of the run method removes successive elements from the agenda and performs their actions. It continues until the agenda is empty:

```
private def next() {
   agenda match {
     case WorkItem(time, action) :: rest =>
        agenda = rest; curtime = time; action()
     case List() =>
   }
}

def run() {
   afterDelay(0) { println("*** simulation started ***") }
   while (!agenda.isEmpty) next()
}
```

**Running the Simulator.** To run the simulator, we still need a way to inspect changes of signals on wires. To this purpose, we write a function probe.

```
def probe(name: String, wire: Wire) {
  wire addAction { () =>
    println(name + " " + currentTime + " new_value = " + wire.getSignal)
  }
}
```

Now, to see the simulator in action, let's define four wires, and place probes on two of them:

```
scala> val input1, input2, sum, carry = new Wire
scala> probe("sum", sum)
sum 0 new_value = false
```

11.4 Summary 99

```
scala> probe("carry", carry)
carry 0 new_value = false
```

Now let's define a half-adder connecting the wires:

```
scala> halfAdder(input1, input2, sum, carry)
```

Finally, set one after another the signals on the two input wires to **true** and run the simulation.

```
scala> input1 setSignal true; run
*** simulation started ***
sum 8 new_value = true

scala> input2 setSignal true; run
carry 11 new_value = true
sum 15 new_value = false
```

#### 11.4 Summary

We have seen in this chapter the constructs that let us model state in Scala – these are variables, assignments, and imperative control structures. State and Assignment complicate our mental model of computation. In particular, referential transparency is lost. On the other hand, assignment gives us new ways to formulate programs elegantly. As always, it depends on the situation whether purely functional programming or programming with assignments works best.

## Chapter 12

# **Computing with Streams**

The previous chapters have introduced variables, assignment and stateful objects. We have seen how real-world objects that change with time can be modeled by changing the state of variables in a computation. Time changes in the real world thus are modeled by time changes in program execution. Of course, such time changes are usually stretched out or compressed, but their relative order is the same. This seems quite natural, but there is a also price to pay: Our simple and powerful substitution model for functional computation is no longer applicable once we introduce variables and assignment.

Is there another way? Can we model state change in the real world using only immutable functions? Taking mathematics as a guide, the answer is clearly yes: A time-changing quantity is simply modeled by a function f(t) with a time parameter t. The same can be done in computation. Instead of overwriting a variable with successive values, we represent all these values as successive elements in a list. So, a mutable variable var x: T gets replaced by an immutable value val x: List[T]. In a sense, we trade space for time – the different values of the variable now all exist concurrently as different elements of the list. One advantage of the list-based view is that we can "time-travel", i.e. view several successive values of the variable at the same time. Another advantage is that we can make use of the powerful library of list processing functions, which often simplifies computation. For instance, consider the imperative way to compute the sum of all prime numbers in an interval:

Note that the variable i "steps through" all values of the interval [start .. end-1].

A more functional way is to represent the list of values of variable i directly as range(start, end). Then the function can be rewritten as follows.

```
def sumPrimes(start: Int, end: Int) =
  sum(range(start, end) filter isPrime)
```

No contest which program is shorter and clearer! However, the functional program is also considerably less efficient since it constructs a list of all numbers in the interval, and then another one for the prime numbers. Even worse from an efficiency point of view is the following example:

To find the second prime number between 1000 and 10000:

```
range(1000, 10000) filter isPrime at 1
```

Here, the list of all numbers between 1000 and 10000 is constructed. But most of that list is never inspected!

However, we can obtain efficient execution for examples like these by a trick:

Avoid computing the tail of a sequence unless that tail is actually necessary for the computation.

We define a new class for such sequences, which is called Stream.

Streams are created using the constant empty and the constructor cons, which are both defined in module scala. Stream. For instance, the following expression constructs a stream with elements 1 and 2:

```
Stream.cons(1, Stream.cons(2, Stream.empty))
```

As another example, here is the analogue of List.range, but returning a stream instead of a list:

```
def range(start: Int, end: Int): Stream[Int] =
  if (start >= end) Stream.empty
  else Stream.cons(start, range(start + 1, end))
```

(This function is also defined as given above in module Stream). Even though Stream.range and List.range look similar, their execution behavior is completely different:

Stream.range immediately returns with a Stream object whose first element is start. All other elements are computed only when they are *demanded* by calling the tail method (which might be never at all).

Streams are accessed just as lists. Similarly to lists, the basic access methods are isEmpty, head and tail. For instance, we can print all elements of a stream as follows.

```
def print(xs: Stream[A]) {
   if (!xs.isEmpty) { Console.println(xs.head); print(xs.tail) }
}
```

Streams also support almost all other methods defined on lists (see below for where their methods sets differ). For instance, we can find the second prime number between 1000 and 10000 by applying methods filter and apply on an interval stream:

```
Stream.range(1000, 10000) filter isPrime at 1
```

The difference to the previous list-based implementation is that now we do not needlessly construct and test for primality any numbers beyond 1013.

**Consing and appending streams.** Two methods in class List which are not supported by class Stream are :: and :::. The reason is that these methods are dispatched on their right-hand side argument, which means that this argument needs to be evaluated before the method is called. For instance, in the case of x::xs on lists, the tail xs needs to be evaluated before :: can be called and the new list can be constructed. This does not work for streams, where we require that the tail of a stream should not be evaluated until it is demanded by a tail operation. The argument why list-append ::: cannot be adapted to streams is analogous.

Instead of x :: xs, one uses Stream.cons(x, xs) for constructing a stream with first element x and (unevaluated) rest xs. Instead of xs ::: ys, one uses the operation xs append ys.

# Chapter 13

# **Iterators**

Iterators are the imperative version of streams. Like streams, iterators describe potentially infinite lists. However, there is no data-structure which contains the elements of an iterator. Instead, iterators allow one to step through the sequence, using two abstract methods next and hasNext.

```
trait Iterator[+A] {
  def hasNext: Boolean
  def next: A
```

Method next returns successive elements. Method hasNext indicates whether there are still more elements to be returned by next. Iterators also support some other methods, which are explained later.

As an example, here is an application which prints the squares of all numbers from 1 to 100.

```
val it: Iterator[Int] = Iterator.range(1, 100)
while (it.hasNext) {
  val x = it.next
  println(x * x)
}
```

#### 13.1 Iterator Methods

Iterators support a rich set of methods besides next and hasNext, which is described in the following. Many of these methods mimic a corresponding functionality in lists.

106 Iterators

**Append.** Method append constructs an iterator which resumes with the given iterator it after the current iterator has finished.

```
def append[B >: A](that: Iterator[B]): Iterator[B] = new Iterator[B] {
  def hasNext = Iterator.this.hasNext || that.hasNext
  def next = if (Iterator.this.hasNext) Iterator.this.next else that.next
}
```

The terms Iterator.this.next and Iterator.this.hasNext in the definition of append call the corresponding methods as they are defined in the enclosing Iterator class. If the Iterator prefix to this would have been missing, hasNext and next would have called recursively the methods being defined in the result of append, which is not what we want.

**Map, FlatMap, Foreach.** Method map constructs an iterator which returns all elements of the original iterator transformed by a given function f.

```
def map[B](f: A => B): Iterator[B] = new Iterator[B] {
  def hasNext = Iterator.this.hasNext
  def next = f(Iterator.this.next)
}
```

Method flatMap is like method map, except that the transformation function f now returns an iterator. The result of flatMap is the iterator resulting from appending together all iterators returned from successive calls of f.

```
def flatMap[B](f: A => Iterator[B]): Iterator[B] = new Iterator[B] {
    private var cur: Iterator[B] = Iterator.empty
    def hasNext: Boolean =
        if (cur.hasNext) true
        else if (Iterator.this.hasNext) { cur = f(Iterator.this.next); hasNext }
        else false
    def next: B =
        if (cur.hasNext) cur.next
        else if (Iterator.this.hasNext) { cur = f(Iterator.this.next); next }
        else error("next on empty iterator")
}
```

Closely related to map is the foreach method, which applies a given function to all elements of an iterator, but does not construct a list of results

```
def foreach(f: A => Unit): Unit =
  while (hasNext) { f(next) }
```

13.1 Iterator Methods 107

**Filter.** Method filter constructs an iterator which returns all elements of the original iterator that satisfy a criterion p.

```
def filter(p: A => Boolean) = new BufferedIterator[A] {
   private val source =
      Iterator.this.buffered
   private def skip =
      { while (source.hasNext && !p(source.head)) { source.next } }
   def hasNext: Boolean =
      { skip; source.hasNext }
   def next: A =
      { skip; source.next }
   def head: A =
      { skip; source.head }
}
```

In fact, filter returns instances of a subclass of iterators which are "buffered". A BufferedIterator object is an iterator which has in addition a method head. This method returns the element which would otherwise have been returned by head, but does not advance beyond that element. Hence, the element returned by head is returned again by the next call to head or next. Here is the definition of the BufferedIterator trait.

```
trait BufferedIterator[+A] extends Iterator[A] {
  def head: A
}
```

Since map, flatMap, filter, and foreach exist for iterators, it follows that for-comprehensions and for-loops can also be used on iterators. For instance, the application which prints the squares of numbers between 1 and 100 could have equivalently been expressed as follows.

```
for (i <- Iterator.range(1, 100))
  println(i * i)</pre>
```

**Zip.** Method zip takes another iterator and returns an iterator consisting of pairs of corresponding elements returned by the two iterators.

```
def zip[B](that: Iterator[B]) = new Iterator[(A, B)] {
   def hasNext = Iterator.this.hasNext && that.hasNext
   def next = (Iterator.this.next, that.next)
}
```

108 Iterators

### 13.2 Constructing Iterators

Concrete iterators need to provide implementations for the two abstract methods next and hasNext in class Iterator. The simplest iterator is Iterator. empty which always returns an empty sequence:

```
object Iterator {
  object empty extends Iterator[Nothing] {
    def hasNext = false
    def next = error("next on empty iterator")
}
```

A more interesting iterator enumerates all elements of an array. This iterator is constructed by the from Array method, which is also defined in the object Iterator

```
def fromArray[A](xs: Array[A]) = new Iterator[A] {
  private var i = 0
  def hasNext: Boolean =
    i < xs.length
  def next: A =
    if (i < xs.length) { val x = xs(i); i += 1; x }
    else error("next on empty iterator")
}</pre>
```

Another iterator enumerates an integer interval. The Iterator.range function returns an iterator which traverses a given interval of integer values. It is defined as follows.

```
object Iterator {
  def range(start: Int, end: Int) = new Iterator[Int] {
    private var current = start
    def hasNext = current < end
    def next = {
      val r = current
      if (current < end) current += 1
        else error("end of iterator")
      r
    }
  }
}</pre>
```

All iterators seen so far terminate eventually. It is also possible to define iterators that go on forever. For instance, the following iterator returns successive integers from some start value<sup>1</sup>.

 $<sup>^{1}</sup>$ Due to the finite representation of type *int*, numbers will wrap around at  $2^{31}$ .

13.3 Using Iterators

109

```
def from(start: Int) = new Iterator[Int] {
   private var last = start - 1
   def hasNext = true
   def next = { last += 1; last }
}
```

### 13.3 Using Iterators

Here are two more examples how iterators are used. First, to print all elements of an array xs: Array[Int], one can write:

```
Iterator.fromArray(xs) foreach (x \Rightarrow println(x))
```

Or, using a for-comprehension:

```
for (x <- Iterator.fromArray(xs))
  println(x)</pre>
```

As a second example, consider the problem of finding the indices of all the elements in an array of doubles greater than some limit. The indices should be returned as an iterator. This is achieved by the following expression.

```
import Iterator._
fromArray(xs)
.zip(from(0))
.filter(case (x, i) => x > limit)
.map(case (x, i) => i)
```

Or, using a for-comprehension:

```
import Iterator._
for ((x, i) <- fromArray(xs) zip from(0); x > limit)
yield i
```

# Chapter 14

# **Lazy Values**

Lazy values provide a way to delay initialization of a value until the first time it is accessed. This may be useful when dealing with values that might not be needed during execution, and whose computational cost is signifficant. As a first example, let's consider a database of employees, containing for each employee its manager and its team.

The Employee class given above will eagerly initialize all its fields, loading the whole employee table in memory. This is certainly not optimal, and it can be easily improved my making the fields lazy. This way we delay the database access until it is really needed, if it is ever needed.

To see what is really happening, we can use this mockup database which shows when records are fetched:

112 Lazy Values

```
3 -> (3, "Jeffrey Eugenides", 1),
4 -> (4, "Mario Vargas Llosa", 1),
5 -> (5, "Julian Barnes", 2))

def team(id: Int) = {
   for (rec <- table.values.toList; if rec._3 == id)
      yield recToEmployee(rec)
}

def get(id: Int) = recToEmployee(table(id))

private def recToEmployee(rec: (Int, String, Int)) = {
   println("[db] fetching " + rec._1)
   Employee(rec._1, rec._2, rec._3)
}
}</pre>
```

The output when running a program that retrieves one employee confirms that the database is only accessed when referring the lazy values.

Another use of lazy values is to resolve the initialization order of applications composed of several modules. Before lazy values were introduced, the same effect was achieved by using **object** definitions. As a second example, we consider a compiler composed of several modules. We look first at a simple symbol table that defines a class for symbols and two predefined functions.

```
class Symbols(val compiler: Compiler) {
  import compiler.types._

val Add = new Symbol("+", FunType(List(IntType, IntType), IntType))
 val Sub = new Symbol("-", FunType(List(IntType, IntType), IntType))

class Symbol(name: String, tpe: Type) {
  override def toString = name + ": " + tpe
 }
}
```

The symbols module is parameterized with a Compiler instance, which provides access to other services, such as the types module. In our example there are only two predefined functions, addition and subtraction, and their definitions depend on the types module.

```
class Types(val compiler: Compiler) {
  import compiler.symtab._

abstract class Type
  case class FunType(args: List[Type], res: Type) extends Type
```

```
case class NamedType(sym: Symbol) extends Type
case object IntType extends Type
}
```

In order to hook the two components together a compiler object is created and passed as an argument to the two components.

```
class Compiler {
  val symtab = new Symbols(this)
  val types = new Types(this)
}
```

Unfortunately, the straight-forward approach fails at runtime because the symtab module needs the types module. In general, the dependency between modules can be complicated and getting the right initialization order is difficult, or even impossible when there are cycles. The easy fix is to make such fields **lazy** and let the compiler figure out the right order.

```
class Compiler {
   lazy val symtab = new Symbols(this)
   lazy val types = new Types(this)
}
```

Now the two modules are initialized on first access, and the compiler may run as expected.

#### **Syntax**

The **lazy** modifier is allowed only on concrete value definitions. All typing rules for value definitions apply for **lazy** values as well, with one restriction removed: recursive local values are allowed.

# Chapter 15

# Implicit Parameters and Conversions

Implicit parameters and conversions are powerful tools for custimizing existing libraries and for creating high-level abstractions. As an example, let's start with an abstract class of semi-groups that support an unspecified add operation.

```
abstract class SemiGroup[A] {
  def add(x: A, y: A): A
}
```

Here's a subclass Monoid of SemiGroup which adds a unit element.

```
abstract class Monoid[A] extends SemiGroup[A] {
  def unit: A
}
```

Here are two implementations of monoids:

```
object stringMonoid extends Monoid[String] {
  def add(x: String, y: String): String = x.concat(y)
  def unit: String = ""
}
object intMonoid extends Monoid[Int] {
  def add(x: Int, y: Int): Int = x + y
  def unit: Int = 0
}
```

A sum method, which works over arbitrary monoids, can be written in plain Scala as follows.

```
def sum[A](xs: List[A])(m: Monoid[A]): A =
```

```
if (xs.isEmpty) m.unit
else m.add(xs.head, sum(m)(xs.tail)
```

This sum method can be called as follows:

```
sum(List("a", "bc", "def"))(stringMonoid)
sum(List(1, 2, 3))(intMonoid)
```

All this works, but it is not very nice. The problem is that the monoid implementations have to be passed into all code that uses them. We would sometimes wish that the system could figure out the correct arguments automatically, similar to what is done when type arguments are inferred. This is what implicit parameters provide.

#### **Implicit Parameters: The Basics**

In Scala 2 there is a new **implicit** keyword that can be used at the beginning of a parameter list. Syntax:

If the keyword is present, it makes all parameters in the list implicit. For instance, the following version of sum has m as an implicit parameter.

```
def sum[A](xs: List[A])(implicit m: Monoid[A]): A =
  if (xs.isEmpty) m.unit
  else m.add(xs.head, sum(xs.tail))
```

As can be seen from the example, it is possible to combine normal and implicit parameters. However, there may only be one implicit parameter list for a method or constructor, and it must come last.

**implicit** can also be used as a modifier for definitions and declarations. Examples:

```
implicit object stringMonoid extends Monoid[String] {
  def add(x: String, y: String): String = x.concat(y)
  def unit: String = ""
}
implicit object intMonoid extends Monoid[Int] {
  def add(x: Int, y: Int): Int = x + y
  def unit: Int = 0
}
```

The principal idea behind implicit parameters is that arguments for them can be left out from a method call. If the arguments corresponding to an implicit parameter section are missing, they are inferred by the Scala compiler. The actual arguments that are eligible to be passed to an implicit parameter are all identifiers X that can be accessed at the point of the method call without a prefix and that denote an implicit definition or parameter.

If there are several eligible arguments which match the implicit parameter's type, the Scala compiler will chose a most specific one, using the standard rules of static overloading resolution. For instance, assume the call

```
sum(List(1, 2, 3))
```

in a context where stringMonoid and intMonoid are visible. We know that the formal type parameter a of sum needs to be instantiated to int. The only eligible value which matches the implicit formal parameter type Monoid[Int] is intMonoid so this object will be passed as implicit parameter.

This discussion also shows that implicit parameters are inferred after any type arguments are inferred.

#### **Implicit Conversions**

Say you have an expression E of type T which is expected to type S. T does not conform to S and is not convertible to S by some other predefined conversion. Then the Scala compiler will try to apply as last resort an implicit conversion I(E). Here, I is an identifier denoting an implicit definition or parameter that is accessible without a prefix at the point of the conversion, that can be applied to arguments of type T and whose result type conforms to the expected type S.

Implicit conversions can also be applied in member selections. Given a selection E.x where x is not a member of the type E, the Scala compiler will try to insert an implicit conversion I(E).x, so that x is a member of I(E).

Here is an example of an implicit conversion function that converts integers into instances of class scala. Ordered:

```
implicit def int2ordered(x: Int): Ordered[Int] = new Ordered[Int] {
  def compare(y: Int): Int =
    if (x < y) -1
    else if (x > y) 1
    else 0
}
```

#### **View Bounds**

View bounds are convenient syntactic sugar for implicit parameters. Consider for instance a generic sort method:

```
def sort[A <% Ordered[A]](xs: List[A]): List[A] =
  if (xs.isEmpty || xs.tail.isEmpty) xs</pre>
```

```
else {
  val {ys, zs} = xs.splitAt(xs.length / 2)
  merge(ys, zs)
}
```

The view bounded type parameter [a <% Ordered[a]] expresses that sort is applicable to lists of type a such that there exists an implicit conversion from a to Ordered[a]. The definition is treated as a shorthand for the following method signature with an implicit parameter:

```
def sort[A](xs: List[A])(implicit c: A => Ordered[A]): List[A] = ...
```

(Here, the parameter name *c* is chosen arbitrarily in a way that does not collide with other names in the program.)

As a more detailed example, consider the merge method that comes with the sort method above:

```
def merge[A <% Ordered[A]](xs: List[A], ys: List[A]): List[A] =
  if (xs.isEmpty) ys
  else if (ys.isEmpty) xs
  else if (xs.head < ys.head) xs.head :: merge(xs.tail, ys)
  else if ys.head :: merge(xs, ys.tail)</pre>
```

After expanding view bounds and inserting implicit conversions, this method implementation becomes:

The last two lines of this method definition illustrate two different uses of the implicit parameter c. It is applied in a conversion in the condition of the second to last line, and it is passed as implicit argument in the recursive call to merge on the last line.

# Chapter 16

# Hindley/Milner Type Inference

This chapter demonstrates Scala's data types and pattern matching by developing a type inference system in the Hindley/Milner style [?]. The source language for the type inferencer is lambda calculus with a let construct called Mini-ML. Abstract syntax trees for the Mini-ML are represented by the following data type of Terms.

```
abstract class Term {}
case class Var(x: String) extends Term {
  override def toString = x
}
case class Lam(x: String, e: Term) extends Term {
  override def toString = "(\\" + x + "." + e + ")"
}
case class App(f: Term, e: Term) extends Term {
  override def toString = "(" + f + " " + e + ")"
}
case class Let(x: String, e: Term, f: Term) extends Term {
  override def toString = "let " + x + " = " + e + " in " + f
}
```

There are four tree constructors: Var for variables, Lam for function abstractions, App for function applications, and Let for let expressions. Each case class overrides the toString method of class Any, so that terms can be printed in legible form.

We next define the types that are computed by the inference system.

```
sealed abstract class Type {}
case class Tyvar(a: String) extends Type {
  override def toString = a
}
case class Arrow(t1: Type, t2: Type) extends Type {
  override def toString = "(" + t1 + "->" + t2 + ")"
}
```

```
case class Tycon(k: String, ts: List[Type]) extends Type {
  override def toString =
    k + (if (ts.isEmpty) "" else ts.mkString("[", ",", "]"))
}
```

There are three type constructors: Tyvar for type variables, Arrow for function types and Tycon for type constructors such as Boolean or List. Type constructors have as component a list of their type parameters. This list is empty for type constants such as Boolean. Again, the type constructors implement the toString method in order to display types legibly.

Note that Type is a **sealed** class. This means that no subclasses or data constructors that extend Type can be formed outside the sequence of definitions in which Type is defined. This makes Type a *closed* algebraic data type with exactly three alternatives. By contrast, type Term is an *open* algebraic type for which further alternatives can be defined.

The main parts of the type inferencer are contained in object typeInfer. We start with a utility function which creates fresh type variables:

```
object typeInfer {
  private var n: Int = 0
  def newTyvar(): Type = { n += 1; Tyvar("a" + n) }
```

We next define a class for substitutions. A substitution is an idempotent function from type variables to types. It maps a finite number of type variables to some types, and leaves all other type variables unchanged. The meaning of a substitution is extended point-wise to a mapping from types to types.

```
abstract class Subst extends Function1[Type,Type] {
    def lookup(x: Tyvar): Type

    def apply(t: Type): Type = t match {
        case tv @ Tyvar(a) => val u = lookup(tv); if (t == u) t else apply(u)
        case Arrow(t1, t2) => Arrow(apply(t1), apply(t2))
        case Tycon(k, ts) => Tycon(k, ts map apply)
    }

    def extend(x: Tyvar, t: Type) = new Subst {
        def lookup(y: Tyvar): Type = if (x == y) t else Subst.this.lookup(y)
    }
}

val emptySubst = new Subst { def lookup(t: Tyvar): Type = t }
```

We represent substitutions as functions, of type Type => Type. This is achieved by making class Subst inherit from the unary function type Function1[Type, Type]<sup>1</sup>. To be an instance of this type, a substitution s has to implement an apply method that takes a Type as argument and yields another Type as result. A function application s(t) is then interpreted as s.apply(t).

The lookup method is abstract in class Subst. There are two concrete forms of substitutions which differ in how they implement this method. One form is defined by the emptySubst value, the other is defined by the extend method in class Subst.

The next data type describes type schemes, which consist of a type and a list of names of type variables which appear universally quantified in the type scheme. For instance, the type scheme  $\forall a \forall b.a \rightarrow b$  would be represented in the type checker as:

```
TypeScheme(List(Tyvar("a"), Tyvar("b")), Arrow(Tyvar("a"), Tyvar("b"))) .
```

The class definition of type schemes does not carry an extends clause; this means that type schemes extend directly class AnyRef. Even though there is only one possible way to construct a type scheme, a case class representation was chosen since it offers convenient ways to decompose an instance of this type into its parts.

```
case class TypeScheme(tyvars: List[Tyvar], tpe: Type) {
  def newInstance: Type = {
     (emptySubst /: tyvars) ((s, tv) => s.extend(tv, newTyvar())) (tpe)
  }
}
```

Type scheme objects come with a method newInstance, which returns the type contained in the scheme after all universally type variables have been renamed to fresh variables. The implementation of this method folds (with /:) the type scheme's type variables with an operation which extends a given substitution s by renaming a given type variable tv to a fresh type variable. The resulting substitution renames all type variables of the scheme to fresh ones. This substitution is then applied to the type part of the type scheme.

The last type we need in the type inferencer is Env, a type for environments, which associate variable names with type schemes. They are represented by a type alias Env in module typeInfer:

```
type Env = List[(String, TypeScheme)]
```

There are two operations on environments. The lookup function returns the type scheme associated with a given name, or **null** if the name is not recorded in the environment.

<sup>&</sup>lt;sup>1</sup> The class inherits the function type as a mixin rather than as a direct superclass. This is because in the current Scala implementation, the Function1 type is a Java interface, which cannot be used as a direct superclass of some other class.

```
def lookup(env: Env, x: String): TypeScheme = env match {
   case List() => null
   case (y, t) :: env1 => if (x == y) t else lookup(env1, x)
}
```

The gen function turns a given type into a type scheme, quantifying over all type variables that are free in the type, but not in the environment.

```
def gen(env: Env, t: Type): TypeScheme =
  TypeScheme(tyvars(t) diff tyvars(env), t)
```

The set of free type variables of a type is simply the set of all type variables which occur in the type. It is represented here as a list of type variables, which is constructed as follows.

```
def tyvars(t: Type): List[Tyvar] = t match {
  case tv @ Tyvar(a) =>
    List(tv)
  case Arrow(t1, t2) =>
    tyvars(t1) union tyvars(t2)
  case Tycon(k, ts) =>
    (List[Tyvar]() /: ts) ((tvs, t) => tvs union tyvars(t))
}
```

Note that the syntax tv @ ... in the first pattern introduces a variable which is bound to the pattern that follows. Note also that the explicit type parameter [Tyvar] in the expression of the third clause is needed to make local type inference work.

The set of free type variables of a type scheme is the set of free type variables of its type component, excluding any quantified type variables:

```
def tyvars(ts: TypeScheme): List[Tyvar] =
  tyvars(ts.tpe) diff ts.tyvars
```

Finally, the set of free type variables of an environment is the union of the free type variables of all type schemes recorded in it.

```
def tyvars(env: Env): List[Tyvar] =
  (List[Tyvar]() /: env) ((tvs, nt) => tvs union tyvars(nt._2))
```

A central operation of Hindley/Milner type checking is unification, which computes a substitution to make two given types equal (such a substitution is called a *unifier*). Function mgu computes the most general unifier of two given types t and u under a pre-existing substitution s. That is, it returns the most general substitution s' which extends s, and which makes s'(t) and s'(u) equal types.

```
def mgu(t: Type, u: Type, s: Subst): Subst = (s(t), s(u)) match {
  case (Tyvar(a), Tyvar(b)) if (a == b) =>
```

```
case (Tyvar(a), _) if !(tyvars(u) contains a) =>
    s.extend(Tyvar(a), u)
case (_, Tyvar(a)) =>
    mgu(u, t, s)
case (Arrow(t1, t2), Arrow(u1, u2)) =>
    mgu(t1, u1, mgu(t2, u2, s))
case (Tycon(k1, ts), Tycon(k2, us)) if (k1 == k2) =>
    (s /: (ts zip us)) ((s, tu) => mgu(tu._1, tu._2, s))
case _ =>
    throw new TypeError("cannot unify " + s(t) + " with " + s(u))
}
```

The mgu function throws a TypeError exception if no unifier substitution exists. This can happen because the two types have different type constructors at corresponding places, or because a type variable is unified with a type that contains the type variable itself. Such exceptions are modeled here as instances of case classes that inherit from the predefined Exception class.

```
case class TypeError(s: String) extends Exception(s) {}
```

The main task of the type checker is implemented by function tp. This function takes as parameters an environment env, a term e, a proto-type t, and a pre-existing substitution s. The function yields a substitution s' that extends s and that turns  $s'(env) \vdash e : s'(t)$  into a derivable type judgment according to the derivation rules of the Hindley/Milner type system [?]. A TypeError exception is thrown if no such substitution exists.

```
def tp(env: Env, e: Term, t: Type, s: Subst): Subst = {
  current = e
  e match {
    case Var(x) =>
      val u = lookup(env, x)
      if (u == null) throw new TypeError("undefined: " + x)
      else mgu(u.newInstance, t, s)
    case Lam(x, e1) =>
      val a, b = newTyvar()
      val s1 = mgu(t, Arrow(a, b), s)
      val env1 = {x, TypeScheme(List(), a)} :: env
      tp(env1, e1, b, s1)
    case App(e1, e2) =>
      val a = newTyvar()
      val s1 = tp(env, e1, Arrow(a, t), s)
      tp(env, e2, a, s1)
```

```
case Let(x, e1, e2) =>
    val a = newTyvar()
    val s1 = tp(env, e1, a, s)
        tp({x, gen(env, s1(a))} :: env, e2, t, s1)
    }
}
var current: Term = null
```

To aid error diagnostics, the tp function stores the currently analyzed sub-term in variable current. Thus, if type checking is aborted with a TypeError exception, this variable will contain the subterm that caused the problem.

The last function of the type inference module, type0f, is a simplified facade for tp. It computes the type of a given term e in a given environment env. It does so by creating a fresh type variable a, computing a typing substitution that makes  $env \vdash e : a$  into a derivable type judgment, and returning the result of applying the substitution to a.

```
def typeOf(env: Env, e: Term): Type = {
   val a = newTyvar()
   tp(env, e, a, emptySubst)(a)
  }
}// end typeInfer
```

To apply the type inferencer, it is convenient to have a predefined environment that contains bindings for commonly used constants. The module predefined defines an environment env that contains bindings for the types of booleans, numbers and lists together with some primitive operations over them. It also defines a fixed point operator fix, which can be used to represent recursion.

```
{"head", gen(Arrow(listType(a), a))},
   {"tail", gen(Arrow(listType(a), listType(a)))},
   {"fix", gen(Arrow(Arrow(a, a), a))}
)
}
```

Here's an example how the type inferencer can be used. Let's define a function showType which returns the type of a given term computed in the predefined environment Predefined.env:

**Exercise 16.0.1** Extend the Mini-ML type inferencer with a letrec construct which allows the definition of recursive functions. Syntax:

```
letrec ident "=" term in term .
```

> (a6->List[a6])

The typing of letrec is as for let, except that the defined identifier is visible in the defining expression. Using letrec, the length function for lists can now be defined as follows.

```
letrec length = \xs.
  if (isEmpty xs)
    zero
    (succ (length (tail xs)))
in ...
```

# **Abstractions for Concurrency**

This section reviews common concurrent programming patterns and shows how they can be implemented in Scala.

### 17.1 Signals and Monitors

**Example 17.1.1** The *monitor* provides the basic means for mutual exclusion of processes in Scala. Every instance of class AnyRef can be used as a monitor by calling one or more of the methods below.

```
def synchronized[A] (e: => A): A
def wait()
def wait(msec: Long)
def notify()
def notifyAll()
```

The synchronized method executes its argument computation e in mutual exclusive mode – at any one time, only one thread can execute a synchronized argument of a given monitor.

Threads can suspend inside a monitor by waiting on a signal. Threads that call the wait method wait until a notify method of the same object is called subsequently by some other thread. Calls to notify with no threads waiting for the signal are ignored.

There is also a timed form of wait, which blocks only as long as no signal was received or the specified amount of time (given in milliseconds) has elapsed. Furthermore, there is a notifyAll method which unblocks all threads which wait for the signal. These methods, as well as class Monitor are primitive in Scala; they are implemented in terms of the underlying runtime system.

Typically, a thread waits for some condition to be established. If the condition does not hold at the time of the wait call, the thread blocks until some other thread has established the condition. It is the responsibility of this other thread to wake up waiting processes by issuing a notify or notifyAll. Note however, that there is no guarantee that a waiting process gets to run immediately after the call to notify is issued. It could be that other processes get to run first which invalidate the condition again. Therefore, the correct form of waiting for a condition C uses a while loop:

```
while (!C) wait()
```

As an example of how monitors are used, here is is an implementation of a bounded buffer class.

```
class BoundedBuffer[A](N: Int) {
    var in = 0, out = 0, n = 0
    val elems = new Array[A](N)

    def put(x: A) = synchronized {
        while (n >= N) wait()
        elems(in) = x ; in = (in + 1) % N ; n = n + 1
        if (n == 1) notifyAll()
    }

    def get: A = synchronized {
        while (n == 0) wait()
        val x = elems(out) ; out = (out + 1) % N ; n = n - 1
        if (n == N - 1) notifyAll()
        x
    }
}
```

And here is a program using a bounded buffer to communicate between a producer and a consumer process.

```
import scala.concurrent.ops._
...
val buf = new BoundedBuffer[String](10)
spawn { while (true) { val s = produceString ; buf.put(s) } }
spawn { while (true) { val s = buf.get ; consumeString(s) } }
}
```

The spawn method spawns a new thread which executes the expression given in the parameter. It is defined in object concurrent . ops as follows.

```
def spawn(p: => Unit) {
  val t = new Thread() { override def run() = p }
  t.start()
```

17.2 SyncVars 129

}

### 17.2 SyncVars

A synchronized variable (or syncvar for short) offers get and put operations to read and set the variable. get operations block until the variable has been defined. An unset operation resets the variable to undefined state.

Here's the standard implementation of synchronized variables.

```
package scala.concurrent
class SyncVar[A] {
 private var isDefined: Boolean = false
 private var value: A = _
 def get = synchronized {
    while (!isDefined) wait()
    value
  }
 def set(x: A) = synchronized {
    value = x; isDefined = true; notifyAll()
 def isSet: Boolean = synchronized {
    isDefined
 def unset = synchronized {
    isDefined = false
 }
}
```

#### 17.3 Futures

A *future* is a value which is computed in parallel to some other client thread, to be used by the client thread at some future time. Futures are used in order to make good use of parallel processing resources. A typical usage is:

```
import scala.concurrent.ops._
...
val x = future(someLengthyComputation)
anotherLengthyComputation
val y = f(x()) + g(x())
```

The future method is defined in object scala.concurrent.ops as follows.

```
def future[A](p: => A): Unit => A = {
```

```
val result = new SyncVar[A]
fork { result.set(p) }
  (() => result.get)
}
```

The future method gets as parameter a computation p to be performed. The type of the computation is arbitrary; it is represented by future's type parameter a. The future method defines a guard result, which takes a parameter representing the result of the computation. It then forks off a new thread that computes the result and invokes the result guard when it is finished. In parallel to this thread, the function returns an anonymous function of type a. When called, this functions waits on the result guard to be invoked, and, once this happens returns the result argument. At the same time, the function reinvokes the result guard with the same argument, so that future invocations of the function can return the result immediately.

### 17.4 Parallel Computations

The next example presents a function par which takes a pair of computations as parameters and which returns the results of the computations in another pair. The two computations are performed in parallel.

The function is defined in object scala.concurrent.ops as follows.

```
def par[A, B](xp: => A, yp: => B): (A, B) = {
  val y = new SyncVar[B]
  spawn { y set yp }
  (xp, y.get)
}
```

Defined in the same place is a function replicate which performs a number of replicates of a computation in parallel. Each replication instance is passed an integer number which identifies it.

```
def replicate(start: Int, end: Int)(p: Int => Unit) {
   if (start == end)
      ()
   else if (start + 1 == end)
      p(start)
   else {
      val mid = (start + end) / 2
      spawn { replicate(start, mid)(p) }
      replicate(mid, end)(p)
   }
}
```

17.5 Semaphores 131

The next function uses replicate to perform parallel computations on all elements of an array.

```
def parMap[A,B](f: A => B, xs: Array[A]): Array[B] = {
  val results = new Array[B](xs.length)
  replicate(0, xs.length) { i => results(i) = f(xs(i)) }
  results
}
```

### 17.5 Semaphores

A common mechanism for process synchronization is a *lock* (or: *semaphore*). A lock offers two atomic actions: *acquire* and *release*. Here's the implementation of a lock in Scala:

```
package scala.concurrent

class Lock {
  var available = true
  def acquire = synchronized {
    while (!available) wait()
    available = false
  }
  def release = synchronized {
    available = true
    notify()
  }
}
```

### 17.6 Readers/Writers

A more complex form of synchronization distinguishes between *readers* which access a common resource without modifying it and *writers* which can both access and modify it. To synchronize readers and writers we need to implement operations *startRead*, *startWrite*, *endRead*, *endWrite*, such that:

- there can be multiple concurrent readers,
- there can only be one writer at one time,
- pending write requests have priority over pending read requests, but don't preempt ongoing read operations.

The following implementation of a readers/writers lock is based on the *mailbox* concept (see Section 17.10).

```
import scala.concurrent._
class ReadersWriters {
  val m = new MailBox
  private case class Writers(n: Int), Readers(n: Int) { m send this }
 Writers(0); Readers(0)
  def startRead = m receive {
    case Writers(n) if n == 0 => m receive {
      case Readers(n) => Writers(0); Readers(n+1)
    }
  }
  def startWrite = m receive {
    case Writers(n) =>
      Writers(n+1)
      m receive { case Readers(n) if n == 0 => }
  def endRead = m receive {
    case Readers(n) => Readers(n-1)
  def endWrite = m receive {
    case Writers(n) => Writers(n-1); if (n == 0) Readers(0)
  }
}
```

### 17.7 Asynchronous Channels

A fundamental way of interprocess communication is the asynchronous channel. Its implementation makes use the following simple class for linked lists:

```
class LinkedList[A] {
  var elem: A = _
  var next: LinkedList[A] = null
}
```

To facilitate insertion and deletion of elements into linked lists, every reference into a linked list points to the node which precedes the node which conceptually forms the top of the list. Empty linked lists start with a dummy node, whose successor is **null**.

The channel class uses a linked list to store data that has been sent but not read yet. At the opposite end, threads that wish to read from an empty channel, register their presence by incrementing the nreaders field and waiting to be notified.

```
package scala.concurrent
```

```
class Channel[A] {
 class LinkedList[A] {
    var elem: A = _
   var next: LinkedList[A] = null
 private var written = new LinkedList[A]
 private var lastWritten = written
 private var nreaders = 0
 def write(x: A) = synchronized {
    lastWritten.elem = x
    lastWritten.next = new LinkedList[A]
    lastWritten = lastWritten.next
    if (nreaders > 0) notify()
  }
 def read: A = synchronized {
    if (written.next == null) {
      nreaders = nreaders + 1; wait(); nreaders = nreaders - 1
    }
    val x = written.elem
   written = written.next
 }
}
```

### 17.8 Synchronous Channels

Here's an implementation of synchronous channels, where the sender of a message blocks until that message has been received. Synchronous channels only need a single variable to store messages in transit, but three signals are used to coordinate reader and writer processes.

```
package scala.concurrent

class SyncChannel[A] {
  private var data: A = _
  private var reading = false
  private var writing = false

def write(x: A) = synchronized {
  while (writing) wait()
  data = x
  writing = true
```

```
if (reading) notifyAll()
  else while (!reading) wait()
}

def read: A = synchronized {
  while (reading) wait()
  reading = true
  while (!writing) wait()
  val x = data
  writing = false
  reading = false
  notifyAll()
  x
}
```

#### 17.9 Workers

Here's an implementation of a *compute server* in Scala. The server implements a future method which evaluates a given expression in parallel with its caller. Unlike the implementation in Section 17.3 the server computes futures only with a predefined number of threads. A possible implementation of the server could run each thread on a separate processor, and could hence avoid the overhead inherent in context-switching several threads on a single processor.

```
import scala.concurrent._, scala.concurrent.ops._
class ComputeServer(n: Int) {
    private abstract class Job {
        type T
        def task: T
        def ret(x: T)
    }
    private val openJobs = new Channel[Job]()
    private def processor(i: Int) {
        while (true) {
            val job = openJobs.read
            job.ret(job.task)
        }
    }
}
```

17.9 Workers 135

```
def future[A](p: => A): () => A = {
    val reply = new SyncVar[A]()
    openJobs.write{
        new Job {
            type T = A
            def task = p
            def ret(x: A) = reply.set(x)
        }
    }
    () => reply.get
}
```

Expressions to be computed (i.e. arguments to calls of future) are written to the openJobs channel. A *job* is an object with

- An abstract type T which describes the result of the compute job.
- A parameterless task method of type t which denotes the expression to be computed.
- A ret method which consumes the result once it is computed.

The compute server creates *n* processor processes as part of its initialization. Every such process repeatedly consumes an open job, evaluates the job's task method and passes the result on to the job's ret method. The polymorphic future method creates a new job where the ret method is implemented by a guard named reply and inserts this job into the set of open jobs. It then waits until the corresponding reply guard is called.

The example demonstrates the use of abstract types. The abstract type t keeps track of the result type of a job, which can vary between different jobs. Without abstract types it would be impossible to implement the same class to the user in a statically type-safe way, without relying on dynamic type tests and type casts.

Here is some code which uses the compute server to evaluate the expression 41 + 1.

```
object Test with Executable {
  val server = new ComputeServer(1)
  val f = server.future(41 + 1)
  println(f())
}
```

#### 17.10 Mailboxes

Mailboxes are high-level, flexible constructs for process synchronization and communication. They allow sending and receiving of messages. A *message* in this context is an arbitrary object. There is a special message TIMEOUT which is used to signal a time-out.

```
case object TIMEOUT
```

var msg = null

Mailboxes implement the following signature.

```
class MailBox {
  def send(msg: Any)
  def receive[A](f: PartialFunction[Any, A]): A
  def receiveWithin[A](msec: Long)(f: PartialFunction[Any, A]): A
}
```

The state of a mailbox consists of a multi-set of messages. Messages are added to the mailbox with the send method. Messages are removed using the receive method, which is passed a message processor f as argument, which is a partial function from messages to some arbitrary result type. Typically, this function is implemented as a pattern matching expression. The receive method blocks until there is a message in the mailbox for which its message processor is defined. The matching message is then removed from the mailbox and the blocked thread is restarted by applying the message processor to the message. Both sent messages and receivers are ordered in time. A receiver r is applied to a matching message m only if there is no other {message, receiver} pair which precedes m, r in the partial ordering on pairs that orders each component in time.

As a simple example of how mailboxes are used, consider a one-place buffer:

17.10 Mailboxes 137

}

We define an internal class for receivers with a test method isDefined, which indicates whether the receiver is defined for a given message. The receiver inherits from class Signal a notify method which is used to wake up a receiver thread. When the receiver thread is woken up, the message it needs to be applied to is stored in the msg variable of Receiver.

```
private val sent = new LinkedList[Any]
private var lastSent = sent
private val receivers = new LinkedList[Receiver]
private var lastReceiver = receivers
```

The mailbox class maintains two linked lists, one for sent but unconsumed messages, the other for waiting receivers.

```
def send(msg: Any) = synchronized {
  var r = receivers, r1 = r.next
  while (r1 != null && !r1.elem.isDefined(msg)) {
    r = r1; r1 = r1.next
  }
  if (r1 != null) {
    r.next = r1.next; r1.elem.msg = msg; r1.elem.notify
  } else {
    lastSent = insert(lastSent, msg)
  }
}
```

The send method first checks whether a waiting receiver is applicable to the sent message. If yes, the receiver is notified. Otherwise, the message is appended to the linked list of sent messages.

```
def receive[A](f: PartialFunction[Any, A]): A = {
  val msg: Any = synchronized {
   var s = sent, s1 = s.next
  while (s1 != null && !f.isDefinedAt(s1.elem)) {
      s = s1; s1 = s1.next
  }
  if (s1 != null) {
      s.next = s1.next; s1.elem
  } else {
      val r = insert(lastReceiver, new Receiver {
         def isDefined(msg: Any) = f.isDefinedAt(msg)
      })
      lastReceiver = r
      r.elem.wait()
      r.elem.msg
```

```
}
f(msg)
```

The receive method first checks whether the message processor function f can be applied to a message that has already been sent but that was not yet consumed. If yes, the thread continues immediately by applying f to the message. Otherwise, a new receiver is created and linked into the receivers list, and the thread waits for a notification on this receiver. Once the thread is woken up again, it continues by applying f to the message that was stored in the receiver. The insert method on linked lists is defined as follows.

```
def insert(1: LinkedList[A], x: A): LinkedList[A] = {
   l.next = new LinkedList[A]
   l.next.elem = x
   l.next.next = l.next
   l
}
```

The mailbox class also offers a method receiveWithin which blocks for only a specified maximal amount of time. If no message is received within the specified time interval (given in milliseconds), the message processor argument f will be unblocked with the special TIMEOUT message. The implementation of receiveWithin is quite similar to receive:

```
def receiveWithin[A](msec: Long)(f: PartialFunction[Any, A]): A = {
 val msg: Any = synchronized {
   var s = sent, s1 = s.next
    while (s1 != null && !f.isDefinedAt(s1.elem)) {
      s = s1; s1 = s1.next
    }
    if (s1 != null) {
      s.next = s1.next; s1.elem
    } else {
     val r = insert(lastReceiver, new Receiver {
          def isDefined(msg: Any) = f.isDefinedAt(msg)
      })
     lastReceiver = r
     r.elem.wait(msec)
     if (r.elem.msg == null) r.elem.msg = TIMEOUT
     r.elem.msg
    }
  }
 f(msg)
```

17.11 Actors 139

```
} // end MailBox
```

The only differences are the timed call to wait, and the statement following it.

#### **17.11 Actors**

Chapter 3 sketched as a program example the implementation of an electronic auction service. This service was based on high-level actor processes that work by inspecting messages in their mailbox using pattern matching. A refined and optimized implementation of actors is found in the scala.actors package. We now give a sketch of a simplified version of the actors library.

The code below is different from the implementation in the scala.actors package, so it should be seen as an example how a simple version of actors could be implemented. It is not a description how actors are actually defined and implemented in the standard Scala library. For the latter, please refer to the Scala API documentation.

A simplified actor is just a thread whose communication primitives are those of a mailbox. Such an actor can be defined as a mixin composition extension of Java's standard Thread class with the MailBox class. We also override the run method of the Thread class, so that it executes the behavior of the actor that is defined by its act method. The ! method simply calls the send method of the MailBox class:

```
abstract class Actor extends Thread with MailBox {
  def act(): Unit
  override def run(): Unit = act()
  def !(msg: Any) = send(msg)
}
```
